ภัทรพงศ์ นิจ้อย : การใช้เทคนิคการดูดกลืนรังสีเอกซเรย์และการจำลองโครงสร้างของระบบแก้ว แมงกานีส ลิเทียม โบเรท (X-RAY ABSORPTION SPECTROSCOPY AND STRUCTURAL SIMULATION OF MANGANESE LITHIUM BORATE-BASED GLASS SYSTEM), อาจารย์ที่ปรึกษา: รองศาสตราจารย์ ดร.ประพันธ์ แม่นยำ, 107 หน้า

คำสำคัญ: เทคนิคการดูดกลืนรังสีเอกซเรย์, การจำลองโครงสร้าง, แก้ว

ในช่วงไม่นานมานี้แก้วที่มีโครงสร้างรากฐานจากโบเรทกำลังได้รับความนิยมในการศึกษาเพื่อที่จะนำมาใช้เป็นอุปกรณ์จัดเก็บพลังงาน เช่น เป็นส่วนประกอบของตัวเก็บประจุแบบยิ่งยวด, เป็นขั้วแคโทดของแบตเตอรี่ เป็นต้น วิทยานิพนธ์ฉบับนี้ได้ศึกษาแก้วที่มีรากฐานจากโบเรท-แมงกานีส-ลิเทียม  $x\text{MnO}_2-(1-x)(\text{LiO}_2-2\text{B}_2\text{O}_3)$  เมื่อ  $x = 0.2, 0.25$  และ  $0.3$  ด้วยเทคนิคทางการดูดกลืนรังสีเอกซเรย์ (XAS), การจำลองพลวัตของโมเลกุล (MD) และเทคนิคการปรับแต่งด้วยวิธีการย้อนกลับของมอนติ-คาร์โล (RMC) ซึ่งแบบจำลองโครงสร้างของแก้วที่ได้จากวิธีการจำลองทางคอมพิวเตอร์ MD และ MD-RMC-XAS สอดคล้องกับผลที่วัดได้จากการทดลอง โดยที่แมงกานีสและออกซิเจนมีเลขโคออดิเนชันอยู่ที่ 4.34, 4.42 และ 4.50 ตามลำดับ ส่วนการศึกษาเลขออกซิเดชันของแมงกานีสในแก้วตัวอย่างพบว่า มีการผสมกันระหว่างเลขออกซิเดชัน  $\text{Mn}^{2+}$  และ  $\text{Mn}^{3+}$  ในอัตราส่วนประมาณ 60:40

PATTARAPONG NIJAPAI : X-RAY ABSORPTION SPECTROSCOPY AND STRUCTURAL SIMULATION OF MANGANESE LITHIUM BORATE-BASED GLASS SYSTEM, THESIS ADVISOR : ASSOC. PROF. PRAPAN MANYAM, Ph.D. 107 PP.

Keyword: XAS, Computer Simulation, Glass

Recently, glasses based on borate have aroused interest in energy storage device technology. For example, they can serve as a supercapacitor component or be used as the cathode in batteries. In this thesis, the structure of manganese lithium borate-based glass, denoted as  $x\text{MnO}_2-(1-x)(\text{Li}_2\text{O}-2\text{B}_2\text{O}_3)$  where  $x$  is 0.2, 0.25, and 0.3, was studied using X-ray absorption spectroscopy (XAS), molecular dynamics (MD) simulation, and reverse Monte Carlo (RMC) refinement methods. A good agreement between the structural models from MD simulation, MD-RMC-XAS method, and the obtained experimental data was achieved. The mean Mn-O coordination numbers were found to be 4.37, 4.42, and 4.50, respectively. The oxidation state of Mn in MLB glasses was determined to be a mixture of  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$  with a ratio of 60:40.

## ACKNOWLEDGEMENTS

The following are individuals to whom I would like to express my sincere gratitude for their support and contribution to this thesis.

Firstly, I extend my heartfelt thanks to my supervisor, Prof. Dr. Rattikorn Yimnirun, for his helpful supervision, inspiration, and encouragement throughout my Ph.D.

Secondly, I would also like to express my appreciation to my advisor, Assoc. Prof. Dr. Prapan Manyam, for the valuable advice and kindness provided.

Next, I extend my gratitude to Dr. Pinit Kidkhunthod for his excellent guidance during the XAS experiments and computer simulation, and to Prof. Dr. Alastair N. Cormack for the invaluable suggestions that helped me refine the simulation process. I would also like to thank Prof. Dr. Cormack for taking good care of me during my stay in Alfred, New York, USA.

In addition, the Novel Glass group collaborated exceptionally well, with significant contributions from Dr. Jessada Khajonrit and Mr. Amornthep Montreeuppathum.

Finally, I express my deepest thanks to my parents, friends, and, most importantly, "my cat" for their inspiration and unwavering support.

Pattarapong Nijapai

## INTRODUCTION

### 1.1 Background

Glasses and glass ceramics are examples of advanced functional materials. These have been elucidated in terms of their characteristics and methodology (Karmakar, 2017). Due to their applications in solid-state batteries, optical detectors, optical fibers, and other fields, glasses are gaining popularity. In comparison to crystal products, glasses offer various advantages, including the flexibility to be manufactured in any size or shape. Lithium borate glasses, among the most researched of all glasses, are notable for their potential applications (Ramteke and Gedam, 2014, Berkemeier et al., 2007, Pye et al., 2012, Rao et al., 1996).

A significant focus lies in the advancement of electrode materials for supercapacitors. The precise capacitance of each supercapacitor material is influenced by various factors, including electrode materials, electrolyte, and others. Concerning electrode potential materials, carbon-based materials exhibit higher capacitance than metal oxide-based pseudo-capacitor materials (Lokhande et al., 2011, Zhao et al., 2013). Manganese oxide compound materials, such as  $Mn_2O_4$ ,  $MnO_2$ , and  $MnO$ , were selected as supercapacitor electrode materials due to their environmental friendliness, cost-effectiveness, a range of oxidation states, and high specific capacitance, reaching 1400 F/g and 1370 F.g<sup>-1</sup> (Qi et al., 2016, Toupin et al., 2004). The Li and Mn elements have garnered interest as potential cathode materials for rechargeable Li-ion batteries, boasting a high energy density of 1000 Wh.kg<sup>-1</sup> and a lower cost compared to  $LiCoO_2$  (Ozoemena and Chen, 2016, Yu and Zhou, 2013). Composite materials of lithium-borate glasses have recently gained attention in the field of energy storage (Afyon et al., 2014).

While crystalline high-capacity metal oxide electrode materials are available, they come with disadvantages such as ion penetration through the crystalline lattice and electrode swelling. Researchers are therefore exploring the use of amorphous glass as an alternative to crystalline electrode materials. Changes in the angle linking network-forming polyhedral bonding, such as the Si-O-Si bond angle (ranging from 125° to 165°) and the P-O-P bond angle (ranging from 123° to 180°) in phosphate glass, are linked to the flexibility of the glass structure. The bond angle in the boroxol ring in the borate structure drastically alters in the case of borate glass. Both of these materials exhibit exceptional ability to shape glass (Stoch, 2001). The vanadium lithium borate-based glasses ( $V_2O_5$ -LiBO<sub>2</sub>) have a high specific capacity of roughly 400 mAh.g<sup>-1</sup>, as per prior studies, and maintain a capacity of 300 mAh.g<sup>-1</sup> for 100 cycles.  $V_2O_5$ -LiBO<sub>2</sub> glasses are being considered as potential cathode materials for Li-ion rechargeable batteries.

The study of glass structure can be highly advantageous in this context. Computer simulations, which enable the examination of a glass in all its microscopic details, are theoretically a valuable tool for investigating the production history dependence of glass properties. Despite this potential, only a limited number of simulations have been conducted to comprehensively address this question.

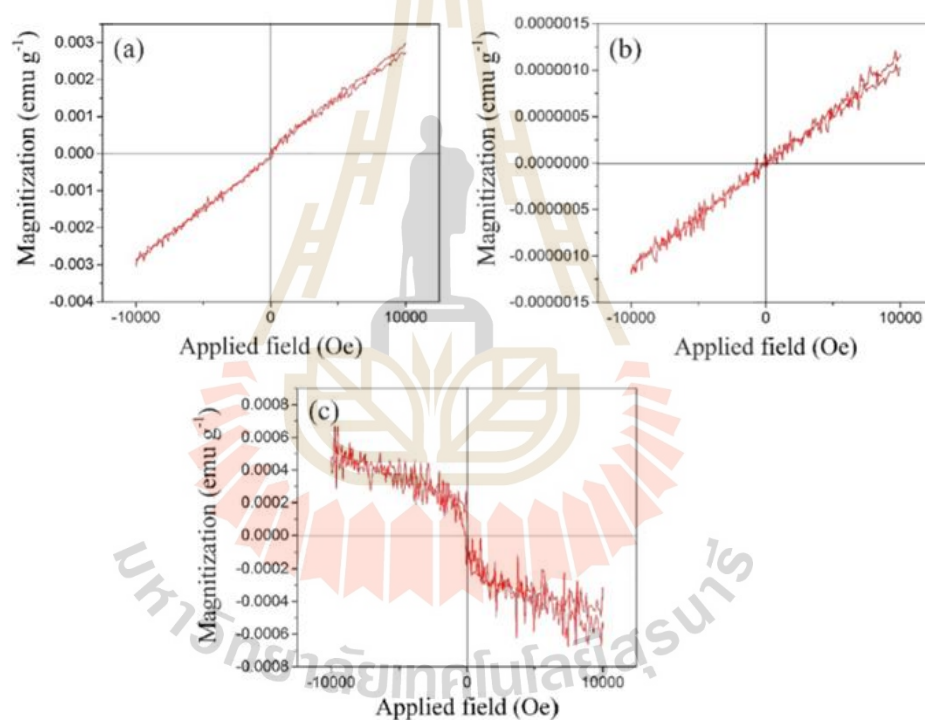

## 1.2 Lithium borate glasses electrode materials

Borate-based glasses were produced and characterized using the VSM method, as outlined by Laorodphan et al. The M-H loops of the glass samples at room temperature are presented in Figure 1.1. The magnetization of the 0.5V<sub>2</sub>O<sub>5</sub>-0.5(Li<sub>2</sub>O-xB<sub>2</sub>O<sub>3</sub>) samples with x=1.0 and 2.0 exhibited a linear relationship with the applied field, indicating their paramagnetic nature. An increase in B<sub>2</sub>O<sub>3</sub> concentration led to a decrease in magnetization (Laorodphan et al., 2016).

S. Afyon has conducted research on vanadium lithium borate glasses as cathode materials in rechargeable lithium-ion batteries. In the context of rechargeable LIBs, a glassy material produced through the Li<sub>2</sub>O-B<sub>2</sub>O<sub>3</sub>-V<sub>2</sub>O<sub>5</sub> method, referred to as V<sub>2</sub>O<sub>5</sub>-LiBO<sub>2</sub>

glass in this document, has been documented. The synthesis involves melting a combination of 80%  $V_2O_5$  and 20%  $LiBO_2$  at  $900^\circ C$ , followed by quenching to room temperature to create the glass content. The resulting cell undergoes discharge with a capacity of 327 mAh/g, followed by a recharge with a capacity of 308 mAh/g in the subsequent step. In a standard  $V_2O_5$ - $LiBO_2$  glass electrode fabrication, the active material comprises 70 wt%  $V_2O_5$  and 20 wt%  $LiBO_2$ . Galvanostatic cells made from such electrodes were measured by discharging to 1.5 V and then charging to 4.0 V at a rate of 50 mA/g. Figure 1.2 illustrates the first ten galvanostatic charge/discharge curves of the  $V_2O_5$ - $LiBO_2$  glass.

**Figure 1.1** Room temperature magnetization hysteresis loop of  $0.5V_2O_5$ - $0.5(Li_2O-xB_2O_3)$  glass samples: (a)  $x=1$ , (b)  $x=2$ , (c)  $x=3$ .

The rate capability of  $V_2O_5$ - $LiBO_2$  glass is depicted in Figure 1.3 between 1.5 and 4.0 V. Capacities of 293, 236, and 180 mAh/g are achieved at rates of 50, 100, and 200 mA/g, respectively. Upon increasing the rate to 400 mA/g on the 35th cycle, the discharge capacity decreases to 125 mAh/g. However, it recovers to 260 mAh/g on the 45th cycle when the rate is reduced back to 50 mA/g. Charging and discharging

experiments for synthesized  $\text{LiMnBO}_3$  (II) within a voltage range of 1.5 - 4.5 V are presented in Figure 1.4. The initial discharge capacity is determined to be  $310 \text{ mAh.g}^{-1}$ , suggesting the possible intercalation and de-intercalation of more than one Li atom per formula unit (f.u) of  $\text{LiMnBO}_3$  (II) (Veena et al., 2019).

Figure 1.2 The first ten charge/discharge curves of the  $\text{V}_2\text{O}_5$ - $\text{LiBO}_2$  glass within a potential window of 1.5 - 4.0 V at 50 mA/g rate (Afyon et al., 2014).

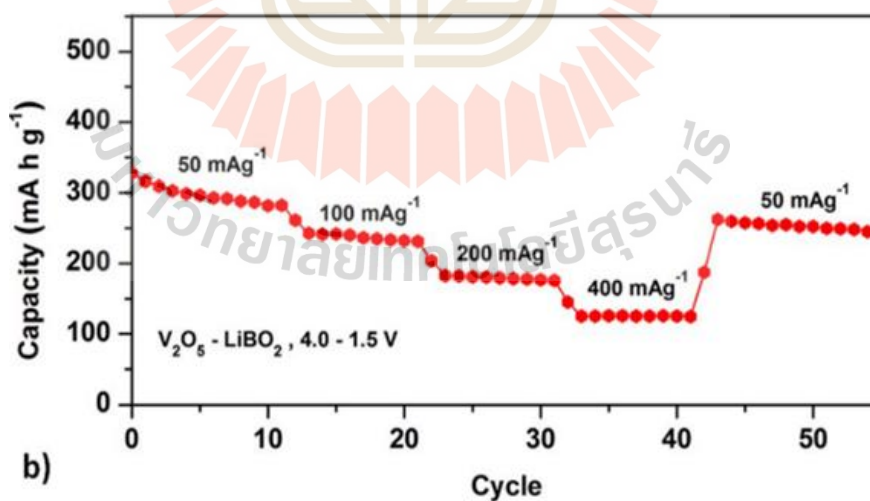

Figure 1.3 The rate capability of the  $\text{V}_2\text{O}_5$ - $\text{LiBO}_2$  glass within 1.5 - 4.0 V at 50, 100, 200 and 400 mA/g rates at room temperature (Afyon et al., 2014).

### 1.3 Structural property of composition of Mn, Li, B and O

The atomic and molecular structures of the  $\text{LiMnBO}_2$  polymorphs in crystals are illustrated in Figure 1.5, depicting Mn triangle constructs with planar hexagons on the edges (Legagneur et al., 2001). The monoclinic trimeric structure, characterized by a single chiral center and trigonal di-pyramidal arrangement, reveals that each Li and Mn site has an upper and lower position relative to the other (Bondareva et al., 1978).

**Figure 1.5** Schematic diagrams of the (a) hexagonal and (b) monoclinic  $\text{LiMnBO}_3$  structure.

After performing ab initio computations and assessing the voltage and energy density of monoclinic and monoclinic  $\text{LiBO}_3$  in terms of both charge state transition and thermodynamic charge-discharge processes, we have gained insights into their stability. The variations in length are presented in Table 1.1, providing a comparative understanding of the charge and discharge stability.

While the hexagonal phase is the computationally expected ground state for  $\text{LiMnBO}_3$ , the energy gap between it and the monoclinic phase is 5 meV per atom, which is close to the numerical precision limit for this process. It is small enough to be readily resolved by entropic results (Kim et al., 2011).

**Table 1.1** Computed properties of the  $\text{LiMnBO}_3$  polymorphs.

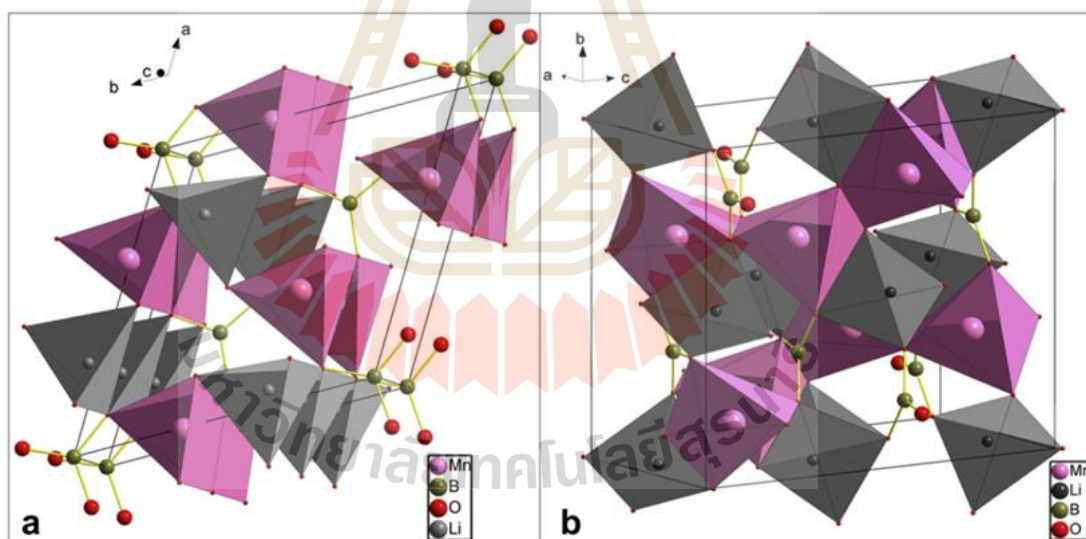

| Phase      | Average voltage (V) | Theoretical Grav. Energy Density (Wh/L) | Theoretical Vol. Energy Density (Wh/L) | Theoretical Capacity (mAh/g) |
|------------|---------------------|---|--|------------------------------|
| Hexagonal  | 4.11                | 912                                     | 2922                                   | 222                          |
| Monoclinic | 3.70                | 822                                     | 2635                                   | 222                          |

The crystal structures of the two  $\text{LiMnBO}_3$  modifications are depicted in Figure 1.6. In the hexagonal phase,  $\text{MnO}_5$  square pyramids are arranged by sharing their equatorial edges.  $\text{MnO}_5$  polyhedral chains extend along the c-axis, interconnected by planar  $\text{BO}_3$  groups. Li atoms exhibit tetrahedral coordination, forming  $\text{LiO}_4$  tetrahedra chains along the c-axis, parallel to those of the square pyramids. In the monoclinic process,  $\text{MnO}_5$  adopts a trigonal bipyramidal geometry, forming polyhedral chains through edge-sharing along the direction. Previous theoretical work indicates that the preferred diffusion direction of Li ions in both phases has a one-dimensional character parallel to the c-axis.

Afyon et al. discovered a lithium-rich compound,  $\text{Li}_7\text{Mn}(\text{BO}_3)_3$ , exhibiting a first discharge capacity of  $280 \text{ mAhg}^{-1}$  with an exchange rate of 3 Li per unit. The synthesis

involved thermalizing  $\text{Li}_2\text{O}$ ,  $\text{MnO}$ , and  $\text{B}_2\text{O}_3$  in precise stoichiometric quantities, resulting in the formation of this novel Li-rich compound. The crystal structure of  $\text{Li}_7\text{Mn}(\text{BO}_3)_3$ , as depicted in Figure 1.7, comprises six separate  $\text{BO}_3^{3+}$  ions, with only one entirely connected to  $\text{Li}^+$  ions, the crystallographically distinct ions having a (B-O) range of 1.31 - 1.43 Å. All additional borate units are linked to two  $\text{Mn}^{2+}$  ions ((Mn-O) = 2.01 - 2.08 Å) and ten  $\text{Li}^+$  ions ((Li-O) = 1.87 - 2.21 Å) in a tetrahedral manner (Afyon et al., 2014).

The  $\text{MnO}_4$ -tetrahedra are arranged in columns that extend down the crystallographic c-axis, as illustrated in Figure 1.8. The sole Li atoms are located in the first coordination spheres of these tetrahedra. Pairs of tetrahedra are joined together by several  $\text{BO}_3^{3+}$  units, and another unit connects the tetrahedra pairs within the columns. The  $\text{BO}_3^{3+}$  groups at the ends of the  $\text{MnO}_4$ -tetrahedra provide the fourth oxygen atoms required for formation.

**Figure 1.6** Crystal structures of  $\text{LiMnBO}_3$ : (a) skew [001] view of the hexagonal phase, (b) skew [100] view of the monoclinic phase.

Compared to other  $\text{Mn}^{2+}$  oxide compounds, manganese's tetrahedral coordination at such a low oxidation state is unique to our knowledge. Typically,  $\text{MO}_6$  octahedra or  $\text{MO}_5$  polyhedra (where  $M = \text{Fe}$ ,  $\text{Mn}$ , and  $\text{Co}$  in  $\text{LiMBO}_3$ ) with trigonal bipyramidal or square-pyramidal geometry have been most frequently observed. This

tetrahedral coordination may contribute to the stabilization of the borate manganate framework when it reaches higher oxidation states ( $\text{Mn}^{n+}$  with  $n > 4$ ) (Afyon et al., 2013).

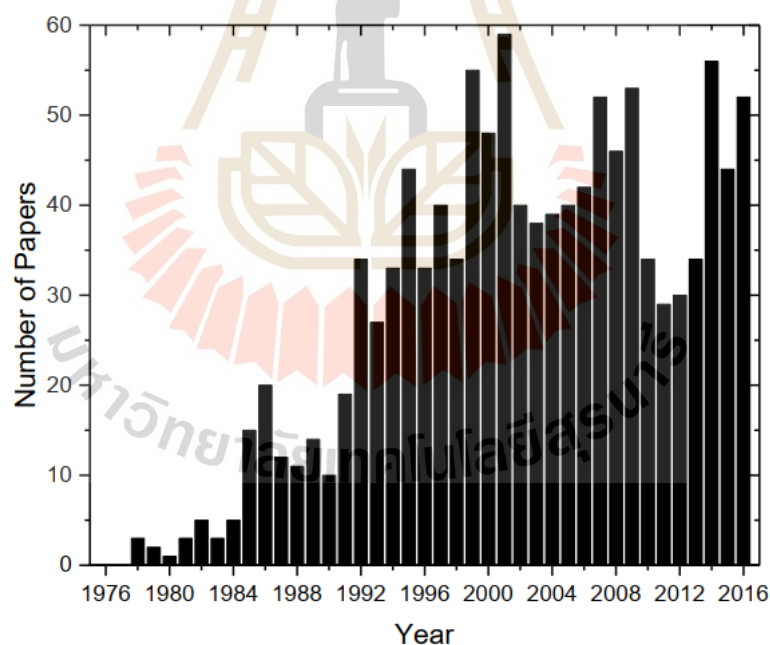

**Figure 1.7** View of the crystal structure of  $\text{Li}_7\text{Mn}(\text{BO}_3)_3$  along  $[001]$  corresponding to the direction of columns of linked  $\text{MnO}_4$  tetrahedra pairs (pink) interconnected by  $\text{BO}_3^{3+}$  ions (B green, O red, Li black).

**Figure 1.8** Columns of pairs of  $\text{MnO}_4$  tetrahedra (pink) interconnected by  $\text{BO}_3^{3+}$  ions extending along the crystallographic  $c$ -axis showing one translational unit (B green, O red) (Afyon et al., 2013).

## 1.4 Characterization technique

In the past, X-ray Absorption Spectroscopy (XAS) has been widely employed to characterize the short-range order and electronic structures of various classes of glassy materials, and in some cases, the medium-range order. Figure 1.9 illustrates the number of papers presenting experimental findings on the structural characterization of glassy materials published between 1975 and 2016. Acronyms such as XAS (X-ray Absorption Spectroscopy), EXAFS (Extended X-ray Absorption Fine Structure), and XANES (X-ray Absorption Near Edge Structure), along with the keywords 'glass' or 'glasses,' were used as search keys in this bibliographic analysis using the ISI Web of Science. The figure indicates that, following a significant initial surge, the number of structural studies on glassy materials peaked at approximately 40 - 50 articles per year around 20 years ago.

**Figure 1.9** Evolution of the number of papers reporting on the structural characterization of glassy materials by XAS spectroscopy. Source: ISI Web of Science.

The X-ray Absorption Spectroscopy (XAS) technique has found application in the characterization of various types of glasses, encompassing oxides, metallic, fluoride,

chalcogenide, and halide glasses. Beyond the analysis of artificial or natural glasses, the XAS approach has been employed in studying glassy materials under standard conditions, exploring their structure in both solid and liquid states. This technique has also been utilized for investigating natural magma glasses (Mastelaro and Zanotto, 2018).

The computer simulation of glass materials has been under development for a long time. In the 1980s and 1990s, Monte Carlo methods played crucial roles in investigating structural changes below and above the glass transition. A notable addition during this period was the development of the Reverse Monte Carlo (RMC) modeling technique. In RMC modeling, atoms in an initial configuration are moved to minimize deviation from experimental structural data, such as X-ray and/or neutron diffraction data, using a standard Monte Carlo (MC) algorithm. A distinctive feature of this method is its reliance not on interatomic potentials, but on experimental Radial Distribution Function (RDF) data. RMC modeling has been successfully applied to structural modeling of liquids and glasses.

On the other hand, the Molecular Dynamics (MD) simulation method is entirely deterministic and provides information about the time dependence of the system's configuration. Similar to the MC method, careful consideration is required when choosing suitable interatomic potentials for calculating force and energy. The methodology of MD simulation has been extensively described (Frenkel et al., 1996), and several monographs summarize MD simulations of glasses. A critical aspect of this method lies in constructing reliable interatomic potentials capable of reasonably reproducing structures and properties. Numerous potentials have been developed, and various potential models are explained in detail in the book by Leach. (Takada and Cormack, 2008).

## 1.5 Thesis outline

This thesis focuses on the fabrication of manganese lithium borate-based glasses using a melt-quenching technique, as outlined in Chapter II. The structural analysis of these glasses has been conducted through Molecular Dynamics (MD) simulation, Reverse Monte Carlo (RMC) modeling, and X-ray Absorption Spectroscopy (XAS), including X-ray Absorption Near Edge Structure (XANES) and Extended X-ray Absorption Fine Structure (EXAFS) techniques. Detailed explanations of these techniques are provided in Chapters III and IV. Chapter V presents the results of the structural study of manganese lithium borate glasses, employing a combination of neutron diffraction, MD simulation, RMC refinement, and the EXAFS technique.

## CHAPTER II

### GLASS FABRICATION BY MELT-QUENCHING TECHNIQUE

#### 2.1 Melt-quenching

In the production of glasses for this study, the melt-quenching method was employed. This widely used technique initiates with the meticulous mixing of raw materials, including oxides or carbonates, to achieve the desired glass composition. Subsequently, the mixed ingredients undergo heating in a furnace, typically exceeding 1300 °C. This elevated temperature results in the formation of a homogeneous glass melt. The next crucial step is quenching, where the molten glass is rapidly cooled, preventing the development of a crystalline structure and resulting in the formation of an amorphous solid-referred to as glass frit.

The obtained glass frit, consisting of small particles, is versatile and can undergo further processing steps based on the intended application. Whether applied directly or subjected to additional processes such as molding, pressing, or sintering, the melt-quenching method provides flexibility in shaping the final glass product.

Key advantages of the melt-quenching method include the creation of homogenous glasses with consistent properties, control over glass composition through the adjustment of raw material mixtures, and suitability for mass production, making it a cost-effective approach for large-scale glass manufacturing.

However, it's important to note that the rapid cooling inherent in melt quenching may introduce imperfections in the glass, such as surface irregularities or internal stresses. Additionally, the technique may not be universally applicable to all glass compositions, particularly those requiring highly controlled crystallinity.

The preparation of the manganese lithium borate (MLB) glass samples used in this investigation, detailed in Section 5.2, was conducted by A. Montreeuppathum and J. Khajonrit (Montreeuppathum et al., 2020, Khajonrit et al., 2018).

## 2.2 Density measurement

In this study, the determination of sample density is conducted through the application of Archimedes' principle. The measurement involves leveraging the buoyancy force when a sample is submerged in a fluid. To establish the density of the submersion liquid, standard steel balls with known and uniform radii are initially employed. These steel balls serve as reference objects, and their densities are used to calibrate the system before measuring the glass samples.

For accurate weight measurements, a micro-balance with a precision of 10  $\mu\text{g}$  is utilized. The density measurement process is illustrated in Figure 2.1 showcasing a hanging basket arrangement to immerse the sample in the liquid. This arrangement ensures the sample is effectively positioned within the liquid medium for precise measurements.

Toluene is chosen as the reference submersion liquid due to its advantageous properties, including low surface tension and low vapor pressure. These properties minimize the likelihood of liquid evaporation during the measurement process, ensuring accuracy.

The relationship between masses and densities measured through these methods is expressed by Equation (2.1), where the density of the sample is determined by comparing its buoyant force in the liquid to the known buoyant forces of reference steel balls. This comprehensive approach provides a robust methodology for obtaining accurate and reliable density measurements for the glass samples studied in this research.

$$\rho_{obj} = \frac{\rho_l m_{obj}}{m_{obj} - m_{obj,l}} \quad (2.1)$$

Where  $\rho_{obj}$  is the density of object.

$\rho_l$  is the density of the submersion liquid.

$m_{obj}$  is the mass of the object in air.

$m_{obj,l}$  is the effective mass measured in the submersed liquid.

Figure 2.1 The schematic of measurement of sample density using Archimedes principle.

## CHAPTER III

### X-RAY ABSORPTION SPECTROSCOPY

#### 3.1 Introduction

X-ray absorption spectroscopy, or XAS, is a widely used method for studying the atomic local structure and electronic states. The terms "X-ray absorption near edge structure" (XANES) and "Extended X-ray Absorption Fine Structure" (EXAFS) are used to describe this, as seen in Figure 3.1. In general, an X-ray excites a core electron in an atom, which can either be promoted to an unoccupied level or ejected from the atom. Both of these methods result in a core hole. According to XAS principles, an electron is ejected by an X-ray source with enough energy for excitation.

A typical XAS system is mainly divided into two parts: the input system and the output system. The input involves the detection of an electron gas ionized signal in the incident chamber ( $I_0$ ). The output captures the electron ionized signal in the transmitted chamber ( $I$ ). The electron X-ray absorptions can be explained by using Beer's law, as shown in Equation 3.1.

$$\mu(E)x = \ln \frac{I_0}{I} \quad (3.1)$$

Where  $\mu(E)$  is transmission coefficient.

$x$  is thickness of sample.

$I_0$  is incident light intensity.

$I$  is transmitted light intensity.

**Figure 3.1** Theoretical and algorithm for XANES and EXAFS spectra (BL-5.2 SLRI).

Following an x-ray absorption event, two primary mechanisms govern the decay of the excited atomic state. The first mechanism, illustrated in Figure 3.2, is x-ray fluorescence, where a higher-energy core-level electron fills the deeper core hole, ejecting an x-ray of well-defined energy. These atom-specific fluorescence energies can be effectively harnessed for identifying atoms in a solution and measuring their concentrations due to their characteristic nature.

The second de-excitation process for the core hole is the Auger Effect. In this phenomenon, an electron descends from a higher electron level, and a second electron is emitted into the continuum, potentially exiting the sample. In the hard x-ray regime ( $> 2$  keV), x-ray fluorescence is more likely to occur than Auger emission. However, for lower-energy x-ray absorption, Auger processes become more prevalent. Both fluorescence and Auger emission methods can be employed to determine the absorption coefficient, although fluorescence is slightly more common, as depicted by the following equation:

$$\mu(E) \propto \frac{I_f}{I_0} \quad (3.2)$$

Where  $I_f$  is the monitored intensity of a fluorescence line (or, again, electron emission) associated with the absorption process.

**Figure 3.2** Schematic of incident, transmitted and fluorescence X-ray beam.

Figure 3.3 presents a visual representation of the photoelectron scattering processes in both the single-scattering regime, specifically Extended X-ray Absorption Fine Structure (EXAFS), and the multiple scattering regime, known as X-ray Absorption Near Edge Structure (XANES). It is important to note that the single scattering approximation is assumed in EXAFS, although multiple scattering can be considered within the EXAFS framework. On the other hand, in XANES, all scattering pathways, categorized based on the number of scattering events (e.g., (3), (4), (5), etc.), contribute to the absorption cross section. In the EXAFS scenario, the photoelectron undergoes scattering interactions with only a single neighboring atom, whereas in XANES, contributions from various scattering events collectively influence the absorption cross section.

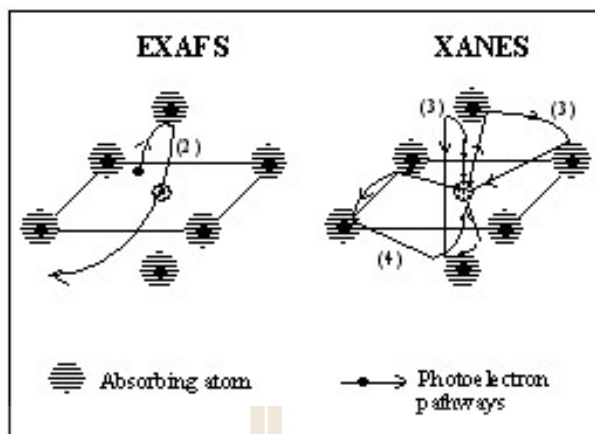

Figure 3.3 XANES and EXAFS phenomena.

In this thesis, X-ray Absorption Spectroscopy (XAS) experiments were conducted at Beam Line 5.2 of the Synchrotron Light Research Institute (as depicted in (Figure 3.4, BL5.2 SLRI, Nakhon Ratchasima, Thailand). The spectra were acquired in the fluorescence mode, utilizing a Ge (220) double crystal setup optimized for K-edge XAS measurements of transition metal elements. The XAS monochromator provided an energy resolution ( $\Delta E/E$ ) of  $2 \times 10^{-4}$  eV.

For data processing, the ATHENA and ATEMIS programs (Ravel and Newville, 2005) were employed. These programs were instrumental in normalizing, correcting, and evaluating each measured X-ray Absorption Near Edge Structure (XANES) and Extended X-ray Absorption Fine Structure (EXAFS) spectrum. The meticulous use of these tools ensures the accuracy and reliability of the XAS data analysis throughout the study.

Figure 3.4 Layout of BL5.2 at the Synchrotron Light research Institute (SLRI) in Thailand.

### 3.2 XANES

A commonly employed term to encompass the examination of spectra obtained through X-ray absorption spectroscopy operations is "X-ray absorption near-edge structure" (XANES). This spectroscopic approach facilitates an element-specific and locally bonding-sensitive study, allowing for the calculation of the partial density of empty states within a molecule. The XANES spectra result from fundamental mechanisms, including the photo absorption of an X-ray into a core level, followed by photoelectron emission and filling of the core hole by an electron in another level. Additionally, fluorescence contributes to the spectra by filling the core hole with an electron in another level, followed by the emission of an Auger electron (Henderson et al., 2014).

Furthermore, X-ray Absorption Near-Edge Structure (XANES) spectra serve as a valuable tool for measuring the oxidation state, phase, and structure of a given sample. This capability is rooted in four distinctive characteristics of XANES spectra, collectively known as the fingerprint technique. The first component is the absorption edge, which is influenced by the sample atom's oxidation state. Typically, as the oxidation state changes, the absorption edge increases by approximately  $\sim 3$  eV. Consequently, XANES becomes a powerful method for determining the oxidation state of each oxide. The second element is the pre-edge, a small peak appearing just before the absorption edge. The peak height is significantly influenced by the symmetry of the atomic structure. For instance, in less symmetrical structures like tetrahedral sites, the peak height is high, whereas in highly symmetrical structures, the peak height is low. Two other distinct features in the XANES spectrum are the spectral spire, also known as the white line, and the area after the spire, induced by multiple scattering. As illustrated in Figure 3.5, XANES proves effective in distinguishing between various oxide phases due to these distinctive features.

Due to the restricted kinetic energy range (5-150 eV) within the XANES region, beginning approximately 5 eV beyond the absorption threshold, the amplitude of photoelectron backscattering by neighboring atoms becomes quite substantial. This

phenomenon results in the predominance of numerous scattering events in XANES spectra. In contemporary scientific applications, the most prevalent use of XANES has been to investigate the oxidation state and coordination environment of transition metals such as Manganese (Mn), Vanadium (V), and Iron (Fe) in various materials, including minerals and amorphous substances like glasses and melts.

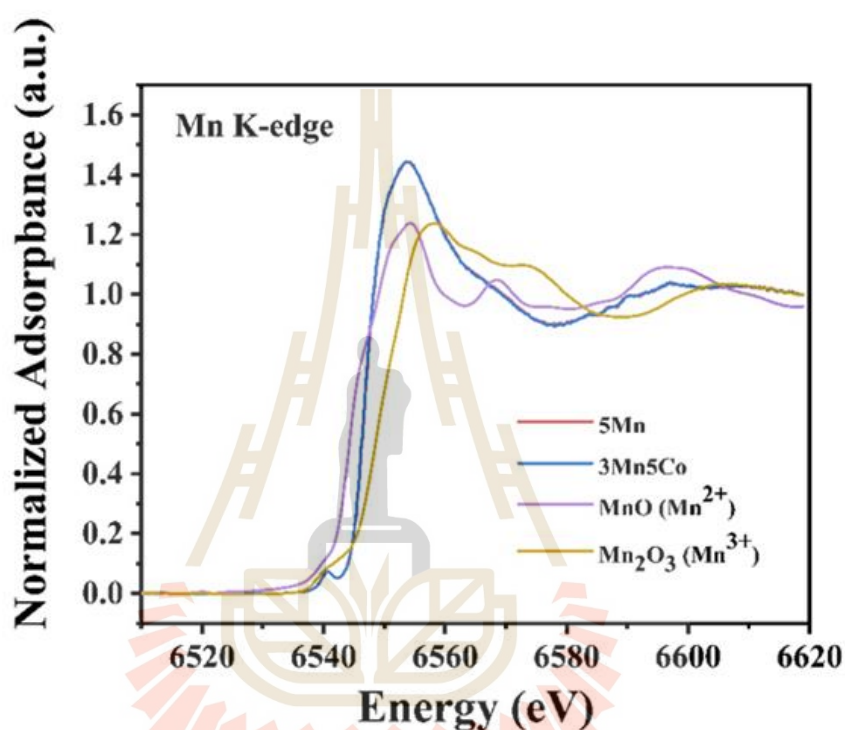

Figure 3.5 Samples from the manganese K-edge XANES spectrum.

In this study, normalized XANES spectra of all samples at the Mn K-edges were compared with those of standard materials exhibiting different Mn oxidation states, including MnO (Mn<sup>2+</sup>), MnO<sub>2</sub> (Mn<sup>4+</sup>), and Mn<sub>2</sub>O<sub>3</sub> (Mn<sup>2+</sup>/Mn<sup>3+</sup>). The determination of the Mn oxidation state ratio was achieved by fitting the linear combination of two distinct oxidation states, derived from the calculation results, to the experimental XANES spectra using ATHENA.

### 3.3 EXAFS

Extended X-ray Absorption Fine Structure (EXAFS) is a phenomenon characterized by the distinctive oscillations observed in x-ray absorption above an x-ray absorption edge. This phenomenon occurs when an incident x-ray photon possesses enough energy to eject an electron from the inner shells of its atom. The ejected electrons form an outgoing photoelectron wave that can be backscattered from nearby atoms. Notably, the characteristic oscillations originate not only from the outgoing photoelectron but also from the backscattered photoelectron. In the high kinetic energy range (150-2000 eV), the final state of the excited photoelectron is predominantly determined by single backscattering events due to the low amplitude of photoelectron scattering. The interaction of the outgoing photoelectron with neighboring atoms is illustrated in Figure 3.6.

The interference between the outgoing and backscattered photoelectron waves is contingent on variations in the electron density of the absorbing atom, which, in turn, is influenced by the energy of the ejected photoelectron. Constructive interference enhances both the electron density and the probability of photon absorption. As a result, the oscillations observed above the edge stem from changes in interference, transitioning from destructive to constructive patterns and vice versa. Additionally, the nature of these oscillations is highly sensitive to the short-range order in materials. Therefore, Extended X-ray Absorption Fine Structure (EXAFS) proves to be a valuable tool, particularly applicable to amorphous systems such as glasses and liquids (Filipponi, 2001, Greaves, 1985). The photoelectron travels as a spherical wave with a wavelength  $\lambda = 2k\pi$  with:

$$k = \sqrt{\frac{2m_e}{\hbar} (E - E_0)} \approx \sqrt{0.2625(E - E_0)} \quad (3.3)$$

Where  $E_0$  is the edge energy.

$E$  is the incident x-ray photon energy.

$k$  is a photoelectron wave number.

**Figure 3.6** Illustration of photoelectron backscattered from the surrounding atom, red circle and blue circles are an absorbing atom and scattering atoms respectively.

In the absence of interference effects, corresponding to isolated atoms, the absorption coefficient is denoted as  $\mu_0(k)$ . The Extended X-ray Absorption Fine Structure (EXAFS) signal is then regarded as the deviation in absorption from this baseline and is conventionally expressed as:

$$\chi(k) = \frac{\mu(k) - \mu_0(k)}{\mu_0(k)} \quad (3.4)$$

Where  $\mu_0(k)$  is the flat absorption of the selected atom.

$\mu(k)$  is the oscillating contribution to the backscattered photoelectron.

The EXAFS oscillation,  $\chi_i(k)$  is the sum of modified sine waves with different frequency and phase from each backscattering coordination shell  $j$ , around the centered atom  $i$  which can be generally written as:

$$\chi_i(k) = \sum_j A_j(k) \sin \psi_{ij}(k) \quad (3.5)$$

Where  $A_j$  is the total backscattering amplitude of the  $j$ th shell of backscattering atoms.

$\psi_{ij}(k)$  is the corresponding total phase function.

Multiple Scattering (MS) involves an event where the photoelectron is scattered by more than one surrounding atom before returning coherently to the absorbing atom. A scattering path is defined by the number of legs, accounting for 2, 3, or 4 legs, through which the photoelectron travels (with the possibility of more paths). For each scattering path, the amplitude and the phase shift are calculated separately (O'day et al., 1994), and the effect of multiple scattering is already included in the EXAFS equation (3.6). MS effects can significantly influence the EXAFS signal, with approximately 90% of the total EXAFS signal contributed by single scattering effects. In certain cases, especially in amorphous materials, only single scattering events may be sufficient to produce an EXAFS spectrum that accurately reflects the local structure of such materials.

**Figure 3.7** Examples of scattering paths consisting of 2, 3 and 4 legs where the arrows note for the legs and the blue and red spheres represent the absorbing atoms and surrounding atoms, respectively.

From the development of scattering theory including the contributions of multiple scattering equation (equation 3.5) can be written to be the standard EXAFS equation as:

$$\chi_i(k) = S_0^2 \sum_j \frac{N_j |f_j(k)|}{k |R_j^2|} \exp(-2k^2 \sigma_j^2) \exp\left(\frac{-2R_j}{\lambda_j(k)}\right) \sin[2kR_j + \phi_{ij}(k)] \quad (3.6)$$

Where  $N_j$  is number of backscattering atoms in the  $j$ th shell.

$R_j$  is distance between the central atom  $i$  and the backscattering atoms in the  $j$ th shell in term of single scattering.

$S_0^2$  is amplitude reduction factor.

$f_j(k)$  is effective amplitude function for each scattering path.

$\exp(-2k^2 \sigma_j^2)$  is Debye-Waller factor in the harmonic approximation with a Gaussian distribution in probability density.

$\sigma_j$  is Debye-Waller parameter accounting for thermal and disorder in structure.

$\lambda_j(k)$  is photoelectron mean free path.

$\exp\left(\frac{-2R_j}{\lambda_j(k)}\right)$  is mean free path factor.

$2kR_j + \phi_{ij}(k)$  is total phase equal to  $\psi_{ij}(k)$ .

$\phi_{ij}(k)$  is phase shift due to the coulomb potential of the central atom  $i$  and the back backscattering atom  $j$ .

In this case the EXAFS signal of disorder materials can be calculated from the partial distribution functions,  $g_{\alpha\beta}(r)$  where the effect of a non-Gaussian distribution of a probability density of atom  $j$  surrounding atom  $i$ ,  $P(r)$ , can be modelled by employing a cumulant expansion method. The effect of non-Gaussian disorder affects

not only result to the Debye-Waller factor, it will affect the phase shifts as well. Equation 3.5 can be written in an another form :

$$\chi_i(k) = \sum_j \frac{F_j(k)}{kr_j^2} \sin(2kr_j + \phi_{ij}(k)) \quad (3.7)$$

Or in the more general form (Koningsberger and Prins, 1987) :

$$\chi_i(k) = \text{Im} \sum_j \frac{S_0^2 F_j(k)}{k} \int \frac{P(r_j, \Lambda)}{r_j^2} \exp\left(i(2kr_j + \phi_{ij}(k))\right) dr_j \quad (3.8)$$

Where

$$P(r_j, \Lambda) = P(r_j) \exp\left(\frac{-2r_j}{\Lambda}\right) \quad (3.9)$$

Consider the integral of equation 3.9  $\int P(r_j) \exp\left(\frac{-2r_j}{\Lambda}\right) dr$  we will get

$$\int P(r_j) \exp\left(\frac{-2r_j}{\Lambda}\right) dr = \frac{1}{R_0} \exp(i2kR_0) \exp(-W + i\phi) \quad (3.10)$$

Where  $R_0 = \langle r \rangle$  is the average value of  $r$ ,  $W$  and  $\phi$  are defined as the terms of  $n^{\text{th}}$  order cumulants  $C_n$  that

$$-W + i\phi = \sum_{n=1} \frac{(2ik)^n}{n!} C_n \quad (3.11)$$

when 
$$W = \sigma^2 \frac{(2k)^2}{2!} - C_4 \frac{(2k)^4}{4!} + \dots \quad (3.12)$$

and 
$$\phi = 2k\Delta R - C_3 \frac{(2k)^3}{3!} + \dots \quad (3.13)$$

In general cases of disorder systems, four cumulants are usually sufficient and from the approximation, equation 3.8 can be written for the disorder EXAFS system as:

$$\chi_i(k) = \text{Im} \sum_j \frac{S_0^2 N_j F_j^{\text{eff}}(k)}{k(R_{0,j} + \Delta R_j)^2} \exp\left[-2k^2 \sigma_j^2 + \frac{2}{3} k^4 C_{4,j}\right] \exp\left[i\left(2k(R_{0,j} + \Delta R_j) - \frac{4}{3} k^3 C_{3,j} + \phi_j^{\text{eff}}(k)\right)\right] \quad (3.14)$$

From equation 3.14, in this study of amorphous system, the EXAFS spectra will be generated using a MD-RMC EXAFS methodology that the cumulant terms will be compensated by the average of hundreds of cluster models (various  $r$ -distances and coordination numbers).

EXAFS signals in this study were also calculated from the MD and MD-RMC configurations by extracting the individual clusters within the restricted distance of the first peak of the partial distribution function,  $g(r)$ , of the absorbing atom and neighboring atoms such as Mn and O atoms. The FEFF code was used to calculate all spectra. After calculating the EXAFS signal for each cluster from the simulation, all the generated EXAFS signals were averaged properly and finally compared with the corrected EXAFS spectra after normalization. Chapters V will show the results of the MD-RMC EXAFS calculation based on this methodology.

## COMPUTER SIMULATION TO CHARACTERIZATION GLASS STRUCTURE

### 4.1 Introduction

In recent years, various techniques have been developed to analyze and generate more detailed structural models of glasses from diffraction data. Theoretical models can be obtained through Molecular Dynamics (MD) simulation and Monte Carlo methods. However, in recent times, data fitting or refinement procedures based on these methods have also been developed, including the Reverse Monte Carlo (RMC) method. In addition to these direct structural probes, spectroscopy techniques, particularly Extended X-ray Absorption Fine Structure (EXAFS), are increasingly applied to structural studies of amorphous systems, especially liquids and glasses. A. Filipponi demonstrated that when carefully applied, EXAFS proves to be a fruitful technique for obtaining information about the local environment of a specifically targeted atom type in a disordered material, in terms of partial pair distribution functions,  $g(r)$  (Filipponi et al., 2000).

In this thesis, I have opted to integrate multiple techniques, namely EXAFS, Molecular Dynamics (MD), and Reverse Monte Carlo (RMC), to achieve a more precise structural model for the manganese lithium borate-base glasses discussed earlier. Enhanced structural models for these glasses are particularly valuable in the context of borate-base glasses, primarily due to their electrical properties and potential applications as cathode materials (Yamada et al., 2010). Hence, in this chapter, a fundamental improved structural model for these glasses will be established by showcasing the amalgamation of several techniques.

## 4.2 Molecular Dynamic simulation

Molecular Dynamics (MD) simulation is a theoretical tool used for modeling the detailed microscopic behavior of various systems, encompassing glasses, liquids, solids, polymers, surfaces, and clusters. In an MD simulation, the classical equations of motion governing the microscopic time evolution of a system with many bodies are numerically solved, considering the appropriate boundary conditions for the system's geometry or symmetry (Bush et al., 1994, Woodley et al., 1999). This method allows the monitoring of microscopic mechanisms of energy and mass transfer in chemical processes, enabling the calculation of dynamical properties such as absorption spectra, rate constants, and transport properties. Additionally, MD simulation can be employed to sample from a statistical mechanical ensemble and determine equilibrium properties (see Figure 4.1). These properties include average thermodynamic quantities (pressure, volume, temperature, etc.), structure, and free energies along reaction paths (Alder and Wainwright, 1959).

In this thesis, a pair potential known as Buckingham Potentials was employed using the MD simulation package DL\_POLY version 4.09 (Todorov et al., 2006). Equation 4.1 illustrates the potentials utilized in this simulation.

$$\varphi_{ij}(r) = A_{ij} \exp\left(\frac{-r_{ij}}{\rho_{ij}}\right) - \frac{C_{ij}}{r_{ij}^6} + \frac{q_i q_j}{4\pi\epsilon_0 r_{ij}} \quad (4.1)$$

Where  $\rho_{ij}$ ,  $A_{ij}$  and  $C_{ij}$  are the parameters derived from an empirical calculation. In this, the first two terms are the Buckingham potentials, and the last term denotes the Coulomb potentials.

Figure 4.1 Simplified schematic of the Molecular Dynamic algorithm.

### 4.3 Reverse Monte Carlo refinement

The basic concept of the RMC technique is straightforward. It operates with a box of atoms at a plausible sample density. Once a satisfactory fit is achieved, all atoms are randomly moved while the structure factors are generated and compared to the data. Typically, the input data consists of neutron diffraction, X-ray diffraction, Extended X-ray Absorption Fine Structure (EXAFS), and Nuclear Magnetic Resonance (NMR). If the fit is unsatisfactory, the atoms are randomly repositioned, recalculating the structure factors with each move until a minimum is attained.

The modeling involves a configuration of atoms in a box with periodic boundary conditions. The pair distribution function  $g^C(\mathbf{r})$  and total structure factor  $A^C(Q)$  of the

configuration are calculated and compared to the experimentally determined functions  $g^E(r)$  or  $A^E(Q)$ . Following each random move of the atoms in the box,  $A^C(Q)$  is compared to  $A^E(Q)$  (or  $g^C(r)$  is compared to  $g^E(r)$ ), and a decision is made to accept or reject the move, as illustrated in Figure 4.2 below.

During the RMC modeling of the configuration, several constraints can be applied. One commonly used constraint is related to the closest distance of approach between two atoms. Chemical information about bond lengths may prohibit atoms from coming too close. For each pair of atom types, a closest approach distance can be specified. The modeled configuration provides information such as partial pair distribution functions, angular distributions, and insights into the likely locations of atoms (Gereben et al., 2007a).

The RMC technique is predominantly employed for modeling diffraction and EXAFS results. In principle, any experimental technique can be simulated if the measured signal can be expressed as a function of atomic coordinates. When initiating the RMC technique, the initial RMC configuration is constructed from the output configuration of the MD simulation. This is done because obtaining a structure that closely resembles reality is remarkably straightforward when considering only extremely minor atom movements. This process, known as RMC-refinement, is highly effective and is principally employed in this thesis.

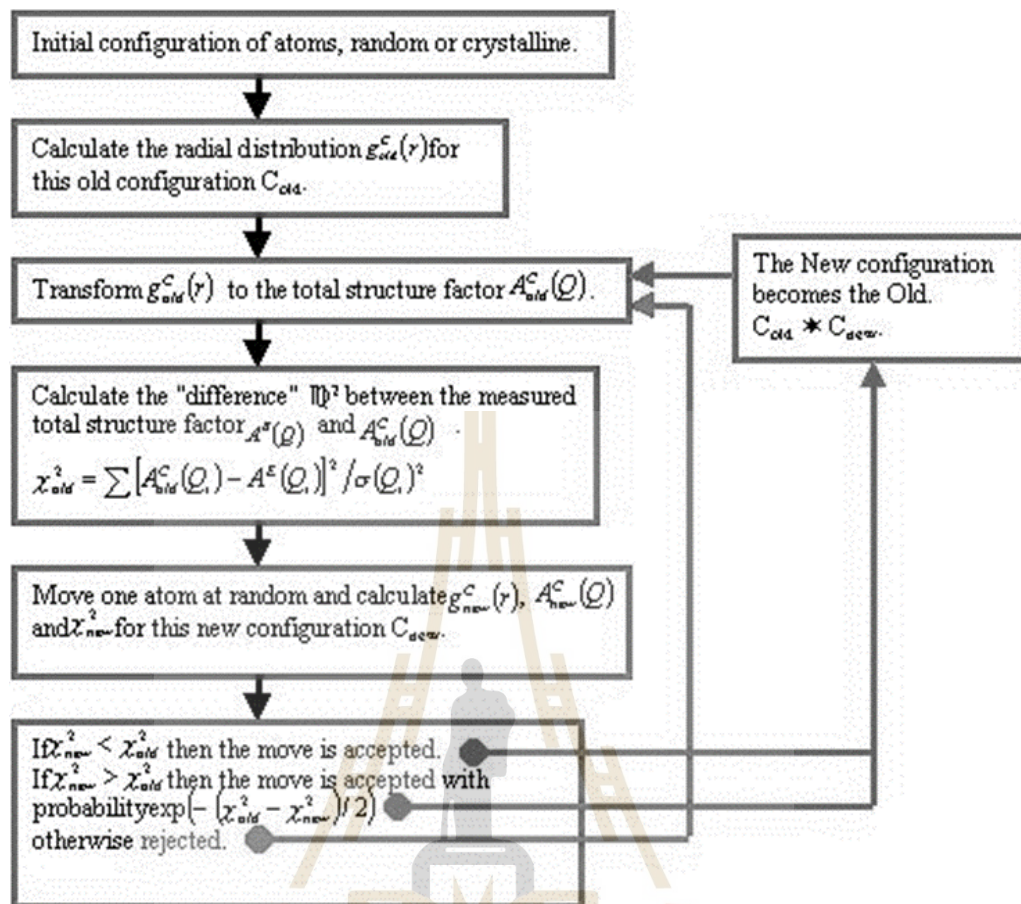

Figure 4.2 Reverse Monte Carlo algorithm.

#### 4.4 FEFF calculation

A comprehensive approach to XAS, encompassing XANES and EXAFS, along with various other x-ray spectroscopies, has become feasible through calculations rooted in standard quasiparticle theory and the RSGF formalism. Typically, simplified models are utilized in these calculations to incorporate many-body effects. Recent theoretical advancements enable the efficient calculation of crucial many-body damping factors in these core-level x-ray spectroscopies using ab initio techniques (Rehr and Albers, 2000, Rehr et al., 2009, Rehr et al., 2010).

The outcomes of the FEFF calculations reveal substantial enhancements in amplitude and phase when employing new methods to calculate inelastic losses, self-

energies, and Debye–Waller factors compared to semi-empirical approaches. This improvement is observed for both near-edge spectra (XANES) and EXAFS (Figure 4.3). The approach considers solid-state effects, such as edge shifts, fine structure, and temperature-dependent Debye–Waller factors, and is applicable to general aperiodic materials.

While the system under investigation is amorphous and lacks a conventional unit cell, the FEFF computation methodology remains applicable. In a typical system, a single unit cell is utilized to compute and represent the entire system. However, in an amorphous system, where no distinct unit cell exists, all relevant atoms are treated as though they are at the center of individual unit cells during each calculation to achieve the final outcome of the system.

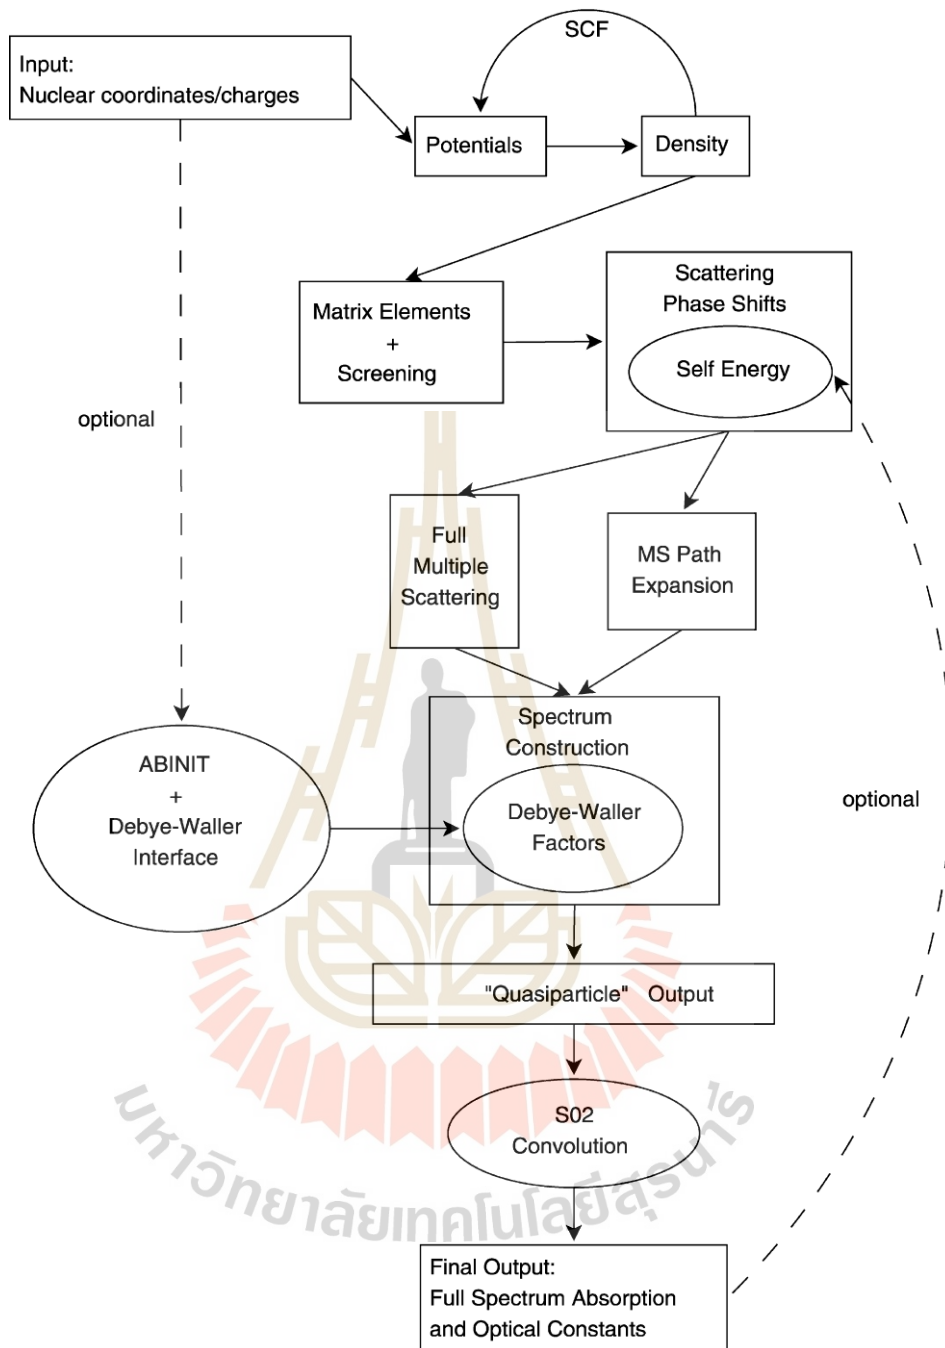

Figure 4.3 Flow diagram for FEFF modules.

## CHAPTER V

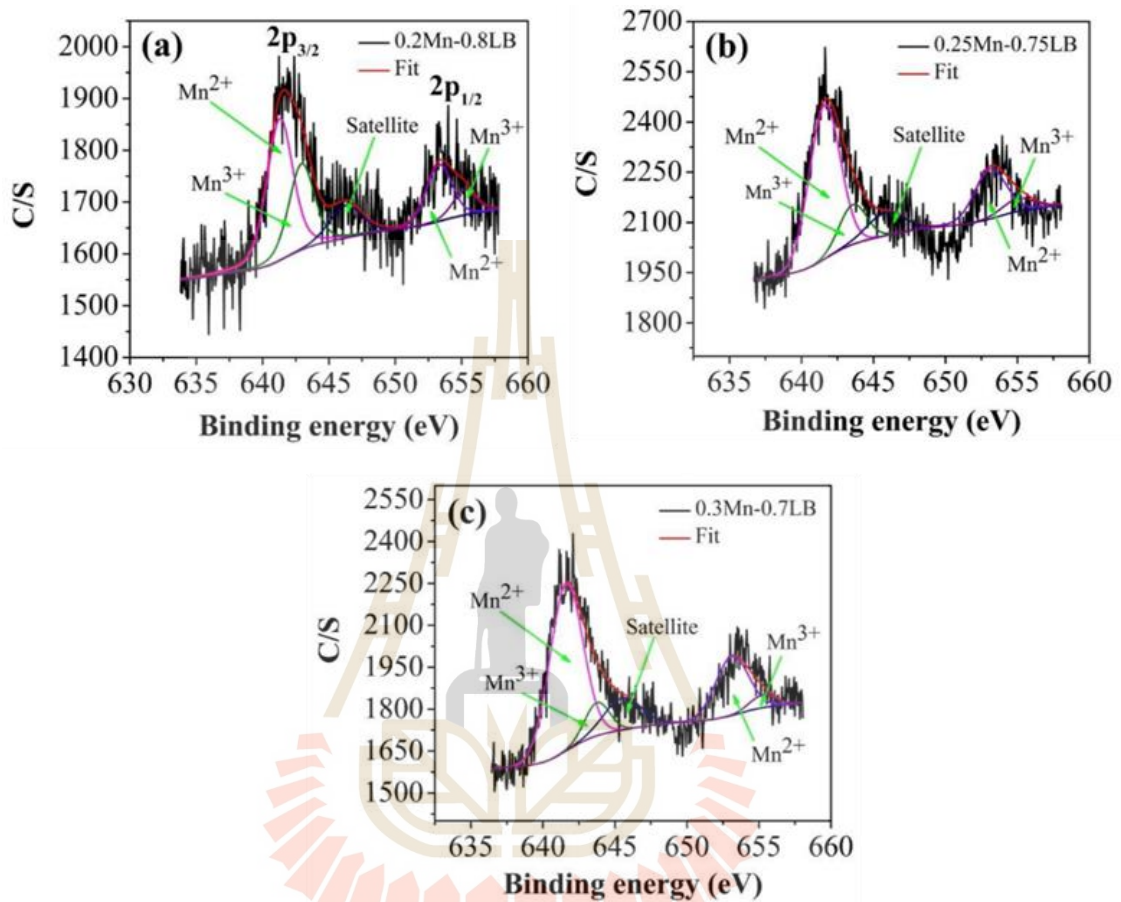

### LOCAL STRUCTURE INVESTIGATION OF MN IN MANGANESE LITHIUM BORATE-BASED GLASS BY COMPUTER SIMULATION AND X-RAY ABSORPTION SPECTROSCOPY

#### 5.1 Introduction

The exploration of novel glass materials has recently garnered significant attention in the field of energy storage resources. While metal oxides in crystalline form, when used as electrode materials, can exhibit high capacities, they also present limitations. In crystalline electrodes, as lithium ions permeate the lattice, structural issues such as lattice expansion and electrode swelling may occur, leading to instabilities during charge/discharge cycles. To address these challenges, manganese lithium borate glasses have been investigated for potential applications as cathode materials. Figure 5.1 illustrates XPS results confirming the mixing of oxidation states of  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$  in all glass samples. The binding energy values for  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$  in the Mn  $2p_{3/2}$  peak are approximately ~641 and ~643 eV, respectively, while in the Mn  $2p_{1/2}$  peak, they are ~653 eV and ~655 eV. The calculated Mn  $2p_{3/2}$  ratios of  $\text{Mn}^{2+}$  (~641 eV)/ $\text{Mn}^{3+}$  (~643 eV) for the 0.2M-0.8(LB), 0.25M-0.75(LB), and 0.3M-0.7(LB) samples are 42.14/24.87%, 54.27/12.23%, and 56.4/8.34%, respectively (Khajonrit et al., 2018).

Dr. Ragupathi's research specifically focused on  $\text{LiMnBO}_3$  (Andersson et al., 2002). When analyzing the  $\text{LiMnBO}_3$  (II) spectrum, it appears as a combination of Li, Mn, and O spectra in Figure 5.2. Figure 5.2(a) indicates a peak at 55.14 eV of binding energy, consistent with similar studies. The binding energies of carbonyl oxygen and M bonding O pairs in Figure 5.2(b) result in peaks in the oxygen range at 532.02 and 529.88 eV, respectively. The  $\text{B}^{1+}$  oxidation state of boron is represented by the B1s peak in Figure

Figure 5.2(c) at 191.24 eV. Figure 5.2(d) displays Mn (2p) spectra, with binding energies of 642.47 and 653.97 eV corresponding to Mn ( $2p_{3/2}$ ) and Mn ( $2p_{1/2}$ ) energy levels, respectively.

**Figure 5.1** XPS profiles of glass samples: (a)  $0.2\text{MnO}_2\text{-}0.8(\text{Li}_2\text{O-}2\text{B}_2\text{O}_3)$ , (b)  $0.25\text{MnO}_2\text{-}0.75(\text{Li}_2\text{O-}2\text{B}_2\text{O}_3)$ , and (c)  $0.30\text{MnO}_2\text{-}0.70(\text{Li}_2\text{O-}2\text{B}_2\text{O}_3)$  (J.Khajornrit et al., 2018).

To gain deeper insights into the nature of inclusions in these glasses, glass samples were fabricated with compositions  $x\text{MnO}_2\text{-(}1\text{-}x\text{)(Li}_2\text{O-}2\text{B}_2\text{O}_3)$ , where  $x$  is 0.2, 0.25, and 0.3, using melt-quenching techniques. X-ray Absorption Spectroscopy (XAS) measurements were employed to investigate the inclusions within the glasses. Additionally, Molecular Dynamics (MD) simulation and Reverse Monte Carlo (RMC) refinement, utilizing Extended X-ray Absorption Fine Structure (EXAFS) data, were employed to reveal detailed information about the local structure concerning manganese in the glasses.

**Figure 5.2** XPS spectra of  $\text{LiMnBO}_3$  (III) materials (a) Li 1s, (b) O 1s, (c) B 1s, and (d) Mn 2p (Andersson et al., 2002).

## 5.2 Experimental method

### 5.2.1 Sample preparation

The manganese-lithium-borate glasses were prepared using the melt-quench technique, involving two processes: lithium borate and manganese-lithium borate glass preparation. In the lithium borate preparation, lithium carbonate ( $\text{Li}_2\text{CO}_3$ , 99%) and boric acid ( $\text{H}_3\text{BO}_3$ , 99.8%) were mixed and heated in an electric furnace at 1100 °C for 1 hour. The resulting melts were poured onto a stainless plate, quickly pressed, and then cooled to room temperature (Figure 5.3). For the manganese-lithium borate glass preparation, the obtained lithium borate glass sample and manganese dioxide ( $\text{MnO}_2$ , 99%) were thoroughly ground and mixed to obtain a fine powder and

a homogeneous mixture. Finally, the homogenized powder was heated at 1,150 °C for 1 hour, and the resulting melts were quickly pressed with the stainless plate. The glasses were successfully prepared and exhibited a brown color (Figure 5.4).

**Figure 5.3** The prepared lithium borate glass by melt-quench technique.

**Figure 5.4** The prepared manganese lithium borate glass by melt-quench technique.

### 5.2.2 XAS experiment

To investigate the local environment and behavior of Mn in the manganese-lithium-borate (MLB) glass, X-ray Absorption Spectroscopy (XAS) experiments were conducted at BL-5.2, SLRI. The experiment was set up for Mn K-edge in FL-mode with an edge energy of 6539 eV. The manganese oxidation state was examined through the X-ray Absorption Near Edge Structure (XANES) regions, while the neighboring atoms of manganese were studied qualitatively using Extended X-ray Absorption Fine Structure (EXAFS) spectra.

The XANES data were normalized and compared with standard data using the ATHENA program to analyze XAS results. For a detailed understanding of the local environment around Mn atoms in the glass samples, the EXAFS data of the glass structure were assessed and fitted using the first shell model in the ARTEMIS program.

### 5.2.3 Computer simulation

A molecular dynamic simulation of  $\text{Li}_7\text{Mn}(\text{BO}_3)_3$  was conducted by J. Roos (Roos et al., 2015) using well-established atomistic and Density Functional Theory (DFT) methods. In this study, a MD simulation was performed for  $x\text{MnO}_2-(1-x)(\text{Li}_2\text{O}-2(\text{B}_2\text{O}_3))$  (MLB) where  $x= 0.2, 0.25, \text{ and } 0.3$ , respectively. The DL\_POLY 4.09 molecular dynamics simulation package was employed, and Buckingham potentials with parameters provided by J. Roos et al. were used, starting with a number density of  $2.329 \text{ g/cm}^3$ ,  $2.446 \text{ g/cm}^3$ , and  $2.622 \text{ g/cm}^3$ , respectively. The stoichiometry equation was utilized to represent the atomic number for each element, as shown in the following equation.

$$\frac{g}{MW} = \frac{N}{6.02 \times 10^{23}} \quad (5.1)$$

Where  $g$  is number of density in  $\text{g/cm}^3$ .

$MW$  is molecular weight of each element.

$N$  is number of atoms.

The parameters used in the potential are presented in Table 5.1. Based on XPS evidence suggesting a mixing of oxidation states for Mn, the ion charges of Mn were determined to be 3+ and 2+. With the exception of the O-O interaction, all like-like interactions were assumed to be purely ionic in nature. The simulation commenced from a random configuration in which the interatomic distances were set according to minimum distance chemical constraints.

**Table 5.1** Short-range Buckingham potential parameters for MLB.

| Interaction                        | A (eV)      | $\rho$ (Å) | C (eV Å <sup>6</sup> ) |
|------------------------------------|-------------|------------|------------------------|
| Li <sup>+</sup> - O <sup>2-</sup>  | 638.712146  | 0.290560   | 0.00                   |
| Mn <sup>2+</sup> - O <sup>2-</sup> | 2601.394    | 0.278      | 0.00                   |
| Mn <sup>3+</sup> - O <sup>2-</sup> | 2580.723796 | 0.277521   | 0.00                   |
| B <sup>3+</sup> - O <sup>2-</sup>  | 539.797394  | 0.340031   | 0.00                   |
| O <sup>2-</sup> - O <sup>2-</sup>  | 22764.3     | 0.149      | 46.94                  |

Figure 5.5 illustrates that the initial simulation was conducted using an NPT Berendsen thermostat at 2000K with 0.001 ps time steps. The system equilibrated after 10,000 steps and was run for an additional ten million steps (10 ns). After this equilibration, the simulation temperature was rapidly decreased by -100K using the NPT Berendsen thermostat for each calculation step until 300K, with one million steps (1 ns) each, and the box size was optimized by allowing the system to re-equilibrate into a disordered (glassy) form for 100,000 steps in NVT.

**Figure 5.5** Procedure for molecular dynamics simulation.

To determine the precise ratio between  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$ , the process initiates with a pure  $\text{Mn}^{2+}$  system and then gradually introduces a subsequent 10%  $\text{Mn}^{2+}$  to  $\text{Mn}^{3+}$  in each step until it reaches pure  $\text{Mn}^{3+}$ . Subsequently, the accurate ratio of  $\text{Mn}^{2+}$  to  $\text{Mn}^{3+}$  is established using the ATHENA program's linear combination fitting of XANES spectra of Mn K-edge. These spectra are generated by performing FEFF calculations on all Mn clusters using the FEFF8.2 software. In this process, some O atoms are appropriately removed to neutralize the total charge, as we consider the remaining oxygen in terms of the carbon dioxide generated during the sample melting. The final atomic configuration of the MD simulation serves as the starting point for a Reverse Monte Carlo (RMC) refinement to the experimental data. The structural model generated by the MD simulation is constrained by the use of effective pair potentials. In practice, it is anticipated that three-body interactions will significantly impact the glass's structure. The absence of these interactions is expected to result in significant disparities between the glass structure predicted by the simulation and the experimental findings.

The MD-RMC EXAFS technique requires the RMC coefficient file to generate backscattering factors (amplitudes + phases) using the FEFF algorithm. In this process, the chi.dat file output from FEFF is crucial, where its second column contains

$\chi(k)$ , representing the elementary 'response' due to a single neighbor (Jóvári et al., 2007). Given the limited data from our experiments, we specifically focused on the Mn K-edge. To ensure accurate backscattering factors, the self-consistent field (SCF) card should be activated in the FEFF input file. It's important to note that iterative calculations may not always converge, so adjusting SCF parameters (e.g.,  $n\_scf$  and  $ca$ ) might be necessary to achieve convergence.

Given the scarcity of experimental data, potential parameters were chosen randomly until an optimal set was found before initiating the RMC refinement process. The MD method served as a reliable starting configuration for the Reverse Monte Carlo (RMC) refinement of atom positions within the MD configuration. This aimed to achieve a better fit to the experimental diffraction data.

The MD-RMC refinement procedure was applied to simultaneously refine EXAFS data obtained from both rapidly and slowly quenched MLB glasses. To ensure the correctness of the employed potentials and prevent atoms from diffusing too far from their initial positions, a maximum atom move of 0.05 Å per step was set in the RMC procedure. At the end of the refinement, the deviation of atoms from their initial positions was checked to ensure they had not moved significantly, relative to their ionic sizes. Within a 10 Å cutoff distance, the positions of nearby atoms around Mn were identified, and the FEFF8.2 program calculated the XANES and EXAFS spectra of Mn. The average spectra were then compared with the experimental spectra using an automatic background adjustment in the ATHENA software.

The radial distribution function (RDF,  $g(r)$ ) quantifies the probability of finding a particle at a distance  $r$  from another specified particle. It varies significantly for different states of matter such as solids, gases, and liquids, reflecting the distinctive characteristics of each material. The bulk density, denoted as  $\rho$ , represents the average density across a liquid and remains constant for a given liquid. On the other hand, the local density, denoted as  $\rho(r)$ , signifies the density of the liquid at a specific distance  $r$  from another molecule, relying on the structural arrangement of the liquid. The RDF

was computed in the DL\_POLY software, based on the local density of the system, as expressed in the following equation:

$$g(r) = \frac{dn_r}{4\pi r^2 dr \rho} \quad (5.2)$$

Where  $dn_r$  is a function that computes the number of particles within a shell of thickness  $dr$ .

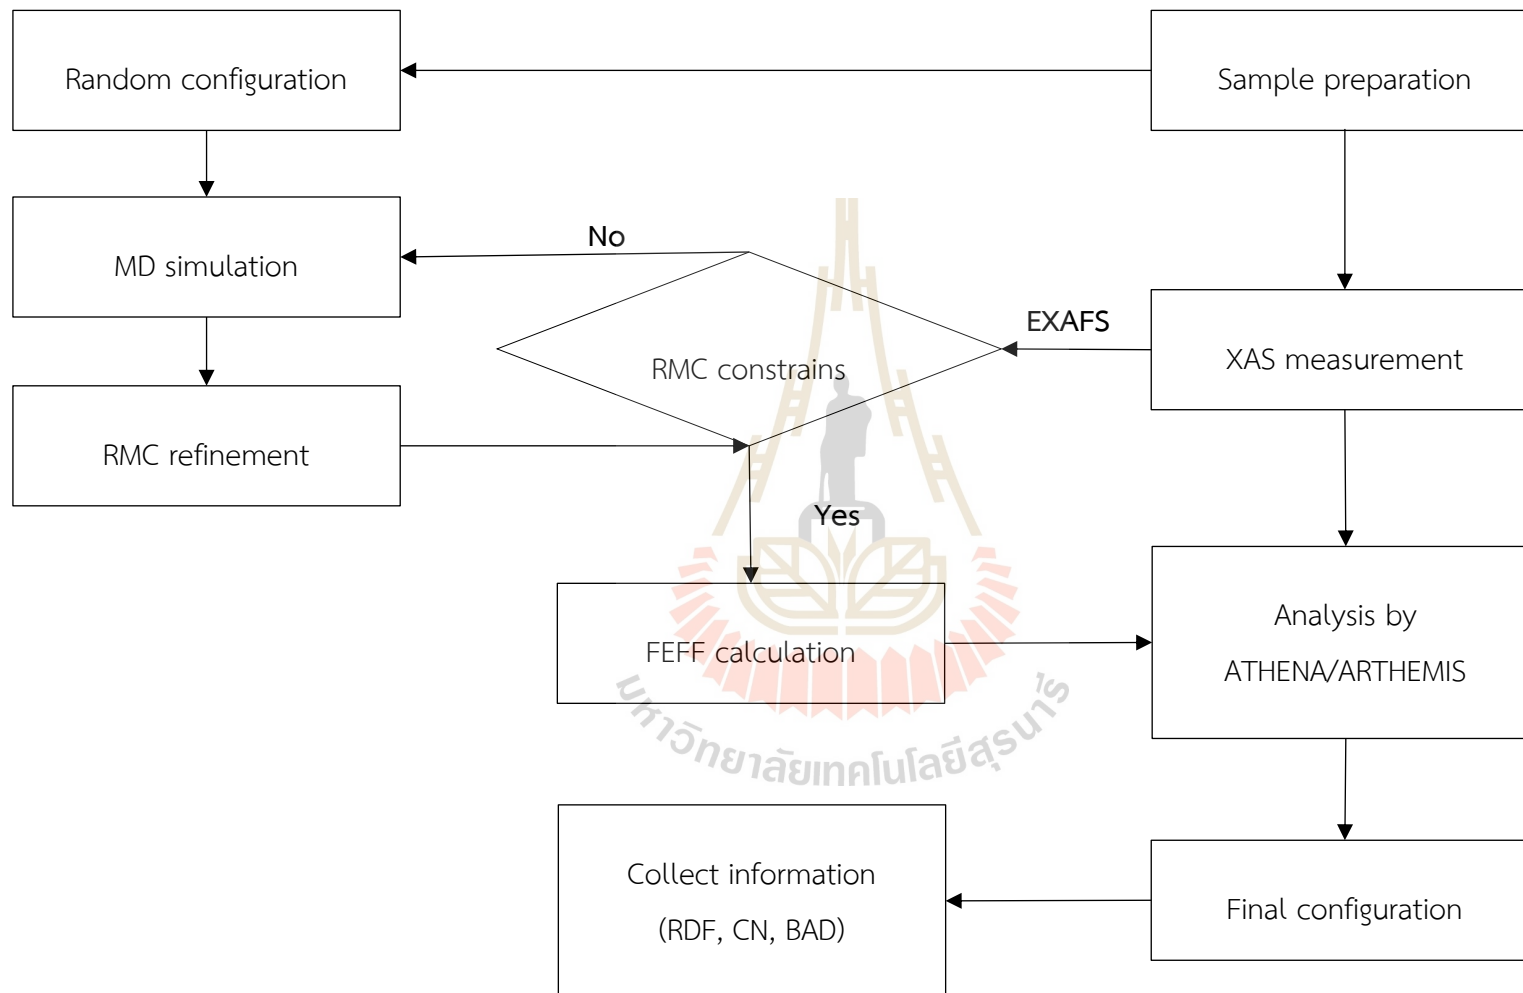

Figure 5.6 Flow chart of this work.

## 5.3 Result

### 5.3.1 XAS result

To investigate the electronic excitations of Mn in the MLB glass structure, X-ray absorption spectroscopy (XAS) was employed. Fluorescence mode experiments were conducted with the sample holder fixed at a 45-degree angle to the incident synchrotron light source. Calibration of the Mn K-edge spectra was accomplished using a standard Mn-foil from BL-5.2, resulting in an edge energy of 6539 eV. XANES spectra were explored in the range of 6510–6600 eV.

The Mn spectra features were further analyzed by comparing them with standard Mn compounds, such as MnO (edge energy 6544 eV), Mn<sub>2</sub>O<sub>3</sub> (edge energy 6548 eV), and MnSO<sub>4</sub>·H<sub>2</sub>O (edge energy 6547 eV). Figure 5.7 the normalized Mn K-edge XANES spectra was performed. Edge energy of all spectra represent to manganese oxidation state which is between MnO and Mn<sub>2</sub>O<sub>3</sub>. While the oscillation feature of all samples is similar to the feature of MnSO<sub>4</sub>·H<sub>2</sub>O, they indicate the mixing oxidation state of the samples. In order of Mn local structure, we are still at a place where we can't go much further with the explanation.

The manganese environment was elucidated through the analysis of the EXAFS spectrum, as depicted in Figure 5.8. The k-space spectrum was transformed into R-space using Fourier transformations within the wavenumber range of 3-9 Å<sup>-1</sup>. Owing to the amorphous nature of the material, the R-space spectrum exhibited a predominant intensity region, specifically the first shell intensity within the range of 1-2 Å, corresponding to oxygen, as illustrated in Figure 5.9.

The parameters derived from the EXAFS fitting, including interatomic distances (R), model coordination numbers, and Debye-Waller factors ( $\sigma^2$ ), are presented in Table 5.2. The variation in the interatomic distance of Mn-O with higher Mn content is attributed to the smaller atomic radius of Mn<sup>2+</sup> (83 pm) compared to Mn<sup>3+</sup> (64 pm).

Figure 5.7 XANES spectra of Mn K-edge of  $0.2\text{MnO}_2\text{-}0.8(\text{Li}_2\text{O-}2\text{B}_2\text{O}_3)$ ,  $0.25\text{MnO}_2\text{-}0.75(\text{Li}_2\text{O-}2\text{B}_2\text{O}_3)$  and  $0.3\text{MnO}_2\text{-}0.7(\text{Li}_2\text{O-}2\text{B}_2\text{O}_3)$  glass samples and standard samples.

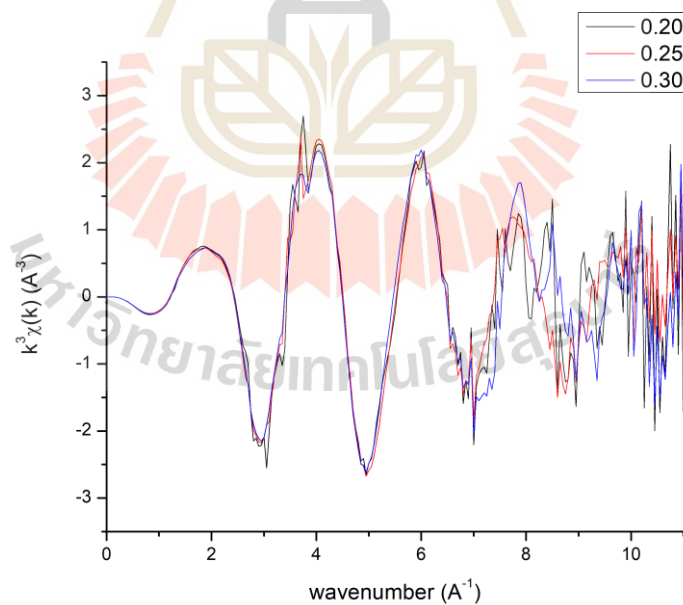

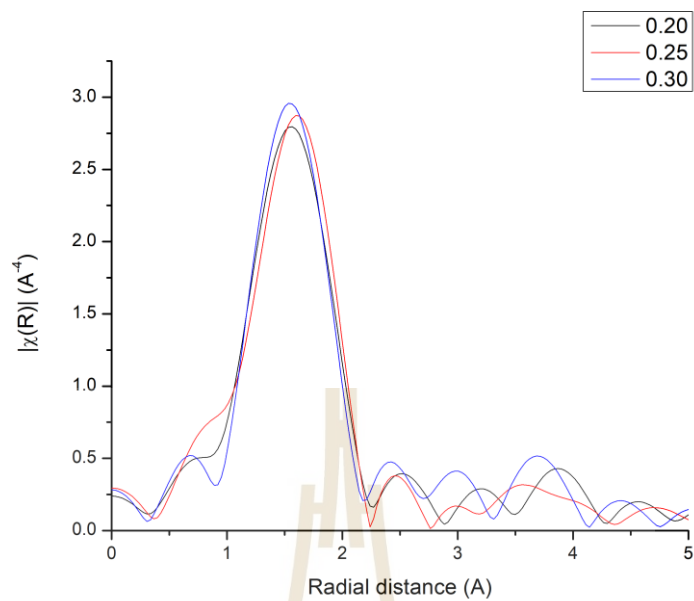

Figure 5.8 The  $k^3\chi(k)$  function extracted from the absorption spectrum for MLB glasses at Mn K-edge.

**Figure 5.9** The corresponding  $|\chi(R)|$  function for MLB glasses at Mn K-edge.

**Table 5.2** EXAFS fitting parameters including interatomic distances (R), coordination numbers and Debye Waller factors ( $\sigma^2$ ) of MLB glass samples.

| Sample | Paths | Coordination number | $\sigma^2$ | R (Å)   |
|--------|-------|---------------------|------------|---------|
| 0.20Mn | Mn-O  | 3.019               | 0.01169    | 2.08524 |
| 0.25Mn | Mn-O  | 2.989               | 0.01169    | 2.08623 |
| 0.30Mn | Mn-O  | 2.911               | 0.01169    | 2.08845 |

## 5.3.2 Computer simulation result

### 5.3.2.1 MD and RMC structure model

The final configurations of 0.2M-0.8LB, 0.25M-0.75LB, and 0.3M-0.7LB are depicted in Figure 5.10-5.12, illustrating  $\text{Mn}^{2+}$  (pink),  $\text{Mn}^{3+}$  (purple), B (dark blue), Li (light blue), and O (red). The final densities of these systems are  $2.5614 \text{ g/cm}^3$ ,  $2.6043 \text{ g/cm}^3$ , and  $2.6650 \text{ g/cm}^3$ , respectively, influenced by the applied NPT Berendsen thermostat in the cool-down process. The models exhibit fully random atomic positions inside the box, confirming an amorphous system. The radial distribution functions of the 15 pairs for the three models are shown in Figure 5.13-5.15. Despite the absence of crystalline peaks in the results, it is confirmed that the system remains amorphous.

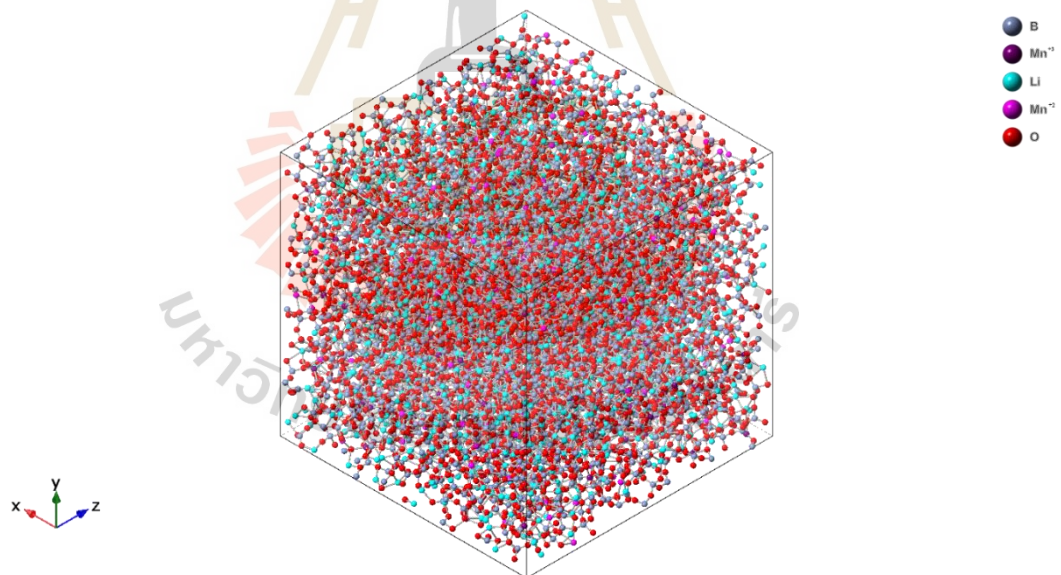

**Figure 5.10** View of the structure of 0.2M-0.8LB glasses which show  $\text{Mn}^{2+}$  (pink),  $\text{Mn}^{3+}$  (purple), B (dark blue), Li (light blue) and O (red).

**Figure 5.11** View of the structure of 0.25M-0.75LB glasses which show Mn<sup>2+</sup> (pink), Mn<sup>3+</sup> (purple), B (dark blue), Li (light blue) and O (red).

**Figure 5.12** View of the structure of 0.3M-0.7LB glasses which show Mn<sup>2+</sup> (pink), Mn<sup>3+</sup> (purple), B (dark blue), Li (light blue) and O (red).

Figure 5.13 15 pairs radial distribution function of 0.2M-0.8LB glasses.

Figure 5.14 15 pairs radial distribution function of 0.25M-0.75LB glasses.

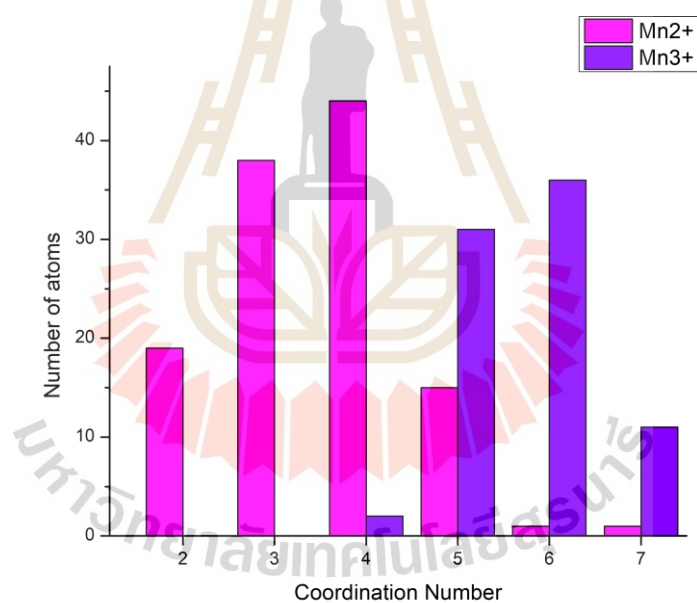

Figure 5.15 15 pairs radial distribution function of 0.3M-0.7LB glasses.

Figure 5.16-5.18 illustrate the distributions of Mn-O coordination numbers calculated from the final configuration models generated by the isolation program (see APPENDIX A). From this distribution, a similarity is observed between  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$ , where approximately 30% of  $\text{Mn}^{2+}$  ions have coordination numbers of 3, around 37% have coordination numbers of 4, approximately 16% have coordination numbers of 5, and about 37% have coordination numbers of 2. For  $\text{Mn}^{3+}$ , around 36% have coordination numbers of 5, approximately 46% have coordination numbers of 6, and about 13% have coordination numbers of 7. Increasing the Mn concentration has a direct impact on the coordination number, with  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$  both experiencing considerable increases in 3-fold, 4-fold for  $\text{Mn}^{2+}$ , and 5-fold, 6-fold for  $\text{Mn}^{3+}$  increments, respectively.

**Figure 5.16** The distributions of  $\text{Mn}^{2+}$ -O (pink) and  $\text{Mn}^{3+}$ -O (purple) coordination numbers obtained from the calculations for 0.2M-0.8LB glasses.

**Figure 5.17** The distributions of Mn<sup>2+</sup>-O (pink) and Mn<sup>3+</sup>-O (purple) coordination numbers obtained from the calculations for 0.25M-0.75LB glasses.

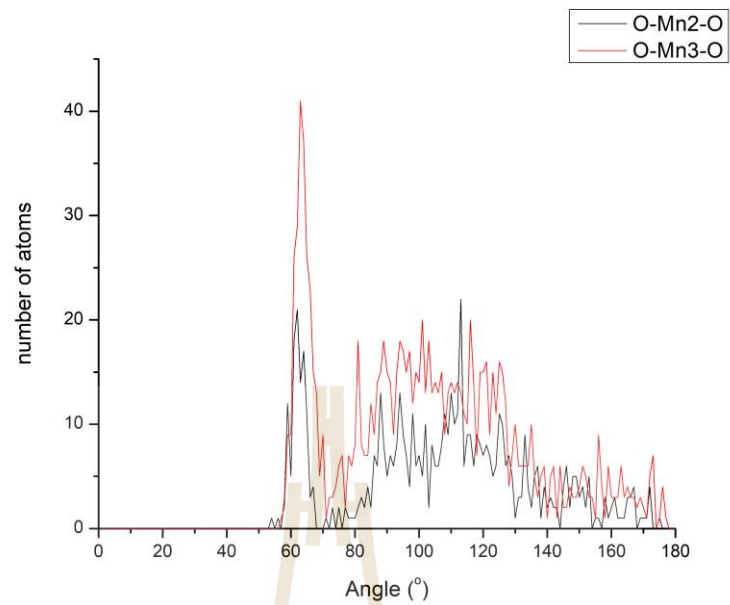

**Figure 5.18** The distributions of Mn<sup>2+</sup>-O (pink) and Mn<sup>3+</sup>-O (purple) coordination numbers obtained from the calculations for 0.3M-0.7LB glasses.

O-Mn<sup>2+</sup>-O and O-Mn<sup>3+</sup>-O bond angle distribution (BAD) values have been calculated and compared with those obtained from the reference configuration (Figure 5.19-5.21) using the program in APPENDIX B. The upper limit of the "bond" has been set to the minimum of the corresponding partial pair correlation functions. A noticeable feature in each case is the peak close to 60°, corresponding to the close packing of three equal hard spheres. Additionally, the BAD shows a broad peak at about 110°. The differences in peak positions of the O-Mn<sup>2+</sup>-O and O-Mn<sup>3+</sup>-O BADs can be qualitatively explained by considering the ratio of atomic radii. Mn<sup>3+</sup> is the smallest among the three atomic species. Therefore, the bond angles centered on Mn<sup>3+</sup> should shift to higher values compared to the O-Mn<sup>2+</sup>-O distribution, as the O atom can move closer to the line joining Mn<sup>2+</sup> atoms.

**Figure 5.19** The angle distributions of O-Mn<sup>2+</sup>-O (black) and O-Mn<sup>3+</sup>-O (red) from the calculations for 0.2M-0.8LB glasses.

**Figure 5.20** The angle distributions of O-Mn<sup>2+</sup>-O (black) and O-Mn<sup>3+</sup>-O (red) from the calculations for 0.25M-0.75LB glasses.

**Figure 5.21** The angle distributions of O-Mn<sup>2+</sup>-O (black) and O-Mn<sup>3+</sup>-O (red) from the calculations for 0.3M-0.7LB glasses.

### 5.3.2.2 FEFF calculation

All atomic positions in each Mn cluster were collected by the FEFF convertor program in APPENDIX C. The XANES spectra of MLB glasses from FEFF calculations are shown in Figure 5.22. The absorption edges of all samples are at 6546 eV, consistent with XPS and XANES linear combination fitting, indicating that Mn is in a mixed oxidation state with a  $\text{Mn}^{2+}$  to  $\text{Mn}^{3+}$  ratio of approximately 6:4. The features of the calculation and the experiment align fairly well. Some of the white line intensity in the computation was slightly higher than that of the experiment due to the absence of O, which was eliminated during the charge neutralization process.

**Figure 5.22** XANES calculation spectra of Mn K-edge of 0.2M-0.8LB, 0.25M-0.75LB and 0.3M-0.7LB glass samples and experiment result.

Figure 5.23-5.25 display the comparison of the  $k^3\chi(k)$  function and the corresponding  $|\chi(R)|$  function between the final calculation and the experiment, showing good agreement. The  $k^3\chi(k)$  was converted to R-space by Fourier Transform (FT) within the wavenumber range of 3 - 9  $\text{\AA}^{-1}$  in the ATHENA program. Despite slight changes in the intensity of R due to a large amount of noisy experimental data beyond

$k = 8 \text{ \AA}^{-1}$ , the initial shell distance remained in good agreement at  $1.5 \pm 0.2 \text{ \AA}$ . This corresponds to  $1.9\text{-}2.1 \text{ \AA}$  when considering the radial size of the core atom. The radial distance of the first shell atom, which points to oxygen atoms, is the only one observed.

**Figure 5.23** The comparison of  $k^3\chi(k)$  function (left) and corresponding  $|\chi(R)|$  function (right) between final calculation (black line) and experiment (red circle) of 0.2M-0.8LB glass.

**Figure 5.24** The comparison of  $k^3\chi(k)$  function (left) and corresponding  $|\chi(R)|$  function (right) between final calculation (black line) and experiment (red circle) of 0.25M-0.75LB glass.

**Figure 5.25** The comparison of  $k^3\chi(k)$  function (left) and corresponding  $|\chi(R)|$  function (right) between final calculation (black line) and experiment (red circle) of 0.3M-0.7LB glass.

## 5.4 Discussion

The final configuration obtained from the MD simulation served as the initial configuration for the MD-RMC-EXAFS, conducted using the RMC++ program (Gereben et al., 2007b). Addressing the challenge of comparing experimental data beyond  $k = 8 \text{ \AA}^{-1}$ , the first shell model from ARTEMIS was employed as the reference data for the RMC method. In Figure 5.26, the MD-RMC-EXAFS is depicted, illustrating the comparison between the RMC-EXAFS (black line) and the first shell model of the 0.2M-0.8LB glass sample (red circle) through the residue. The strong agreement between these datasets underscores the reliability of the potential utilized in the MD process.

The linear combination fitting of the XANES spectrum is presented in Figure 5.27. The two datasets originated from a pure  $\text{Mn}^{2+}$  and  $\text{Mn}^{3+}$  system in the 0.2M-0.8LB glass, which had undergone charge neutralization to form  $\text{MnLi}_8\text{B}_{16}\text{O}_{29}$  and  $\text{MnLi}_{16}\text{B}_{32}\text{O}_{59}$ , respectively. The fitting results suggest that the ratio of  $\text{Mn}^{2+}$  to  $\text{Mn}^{3+}$  is approximately 6:4. Consequently, it implies that the remaining MLB sample has a similar absorption

edge, indicating a consistent Mn composition ratio. However, this result does not entirely align with the XPS findings.

**Figure 5.26** The comparison of the EXAFS data between MD-RMC-EXAFS refinement with the first shell model fitting of EXAFS result for 0.2M-0.8LB glass.

**Figure 5.27** Linear combination fitting (red) of 0.2M-0.8LB glass with pure  $\text{Mn}^{2+}$  (pink) and pure  $\text{Mn}^{3+}$  (green) system.

Figure 5.28-5.30 illustrate the pairs radial distribution of  $\text{Mn}^{2+}\text{-O}$  and  $\text{Mn}^{3+}\text{-O}$ . The distinct peak positions around 2.0 Å for  $\text{Mn}^{3+}$  and 2.1 Å for  $\text{Mn}^{2+}$  are evident in the combined RDF. On the left of each image, the variations in peak position and intensity are displayed, indicating the degree of crystallinity. Despite being less abundant than  $\text{Mn}^{2+}$ ,  $\text{Mn}^{3+}$  has a notable impact. The signal intensity after the peak for  $\text{Mn}^{3+}$  approaches zero, suggesting a more crystalline structure, whereas the signal intensity after the peak for  $\text{Mn}^{2+}$  is slightly higher, indicating that  $\text{Mn}^{2+}$  has more unbounded O around. In the charge transition process,  $\text{Mn}^{2+}$  is thus poised to bind with O and initiate the redox reaction as soon as lithium exits the system.

We can further refine the RDF by summarizing the coordination number and bond angle distribution, as demonstrated earlier. Table 5.3 displays the average coordination number of Mn and the average first shell distance. The increase in Mn content in the MLB glass system has resulted in a higher coordination number. Conversely, the first shell distance is slightly reduced due to the increased presence of Mn atoms, indicating a higher proportion of crystallized  $\text{Mn}^{3+}$ . Figure 5.31 provides an illustration of a Mn cluster with a 6 Å cutoff in the MLB glass system.

**Figure 5.28** Pair radiant distribution function of Mn-O in 0.2M-0.8LB glass for each Mn oxidation state (left) and merged RDF (right).

**Figure 5.29** Pair radiant distribution function of Mn-O in 0.25M-0.75LB glass for each Mn oxidation state (left) and merged RDF (right).

**Figure 5.30** Pair radiant distribution function of Mn-O in 0.3M-0.7LB glass for each Mn oxidation state (left) and merged RDF (right).

**Table 5.3** Average coordination number and first shell distance of MLB glass from calculation

| Sample       | Average coordination number (CN), ( $\pm 0.05$ ) | Average first shell distance (R), ( $\pm 0.005 \text{ \AA}$ ) |
|--------------|--|---|
| 0.2M-0.8LB   | 4.37   | 2.081   |
| 0.25M-0.75LB | 4.42   | 2.080   |
| 0.3M-0.7LB   | 4.50   | 2.078   |

**Figure 5.31** The example of Mn cluster with 6  $\text{\AA}$  cutoff range of  $\text{Mn}^{2+}$ (left) and  $\text{Mn}^{3+}$ (right).

## CHEPTER VI

### CONCLUSION AND SUGGESTION

In this comprehensive investigation, the synergistic application of X-ray Absorption Spectroscopy (XAS), Molecular Dynamics (MD) simulations, and Reverse Monte Carlo (RMC) refinement techniques has been adeptly employed to scrutinize the intricate details of glassy  $x\text{MnO}_2-(1-x)(\text{Li}_2\text{O}-2\text{B}_2\text{O}_3)$ , where  $x = 0.2, 0.25,$  and  $0.3$ . The amalgamation of these four methodologies has yielded results that not only demonstrate a robust agreement with prior research but also accentuate the effectiveness of these techniques in tandem. This study stands as a testament to the capability of these sophisticated tools to derive optimal atomistic models for glassy systems, with implications for advancements in Mn-Li-B-O materials technology.

The investigation delves into the local Mn structures within MLB glass, revealing distinctive geometries in two oxidation states. Notably,  $\text{Mn}^{3+}$  exhibits a proclivity for crystallization compared to  $\text{Mn}^{2+}$ . The coordination number of Mn ions, elucidated through a harmonious integration of XAS, MD simulation, and MD-RMC refinement, portrays a mixed coordination scenario. For instances where  $x = 0.2, 0.25,$  and  $0.3$ , the average coordination numbers are 4.37, 4.42, and 4.50, respectively, corroborating a  $\text{Mn}^{2+}:\text{Mn}^{3+}$  ratio of approximately 6:4. The meticulous choice and verification of potential parameters during the refinement phase emerge as critical considerations. Suggestions for expediting this intricate process include leveraging multiple experimental datasets and custom fitting of potential parameters using a high-performance supercomputer.

Despite the challenges encountered, the amalgamation of XAS, MD simulation, and MD-RMC techniques proves to be a robust and promising approach for obtaining granular structural insights into manganese lithium borate glass. This methodology's

potential extends to future studies investigating other pivotal glass systems, especially those centered around metal borate compositions. Beyond structural elucidation, the atomic structures derived from simulations pave the way for calculating energy band gaps and lithium diffusion coefficients, promising additional avenues for exploration.

Furthermore, this study underscores the potency of Extended X-ray Absorption Fine Structure (EXAFS) spectra as a potent structural constraint for glassy systems. The compelling agreement observed between the MD-RMC configurations and experimental results underscores the importance of meticulous parameter selection for accurate modeling. As this work lays a foundation for advancements in comprehending glass structures and their nuanced properties, it highlights the potential for continued progress in this exciting field.

In addition to the comprehensive findings presented in this study, several key insights and recommendations emerge, contributing to the refinement and enhancement of future investigations in the realm of glassy systems:

- **Accelerating Refinement Process:** The refinement process, particularly in the choice and verification of potential parameters, poses a time-consuming challenge. Future efforts could explore innovative methodologies or algorithms to expedite this stage, potentially leveraging machine learning approaches to predict suitable parameters based on prior data or employing advanced optimization techniques.
- **Diversifying Experimental Datasets:** Enhancing the robustness of the MD-RMC refinement process could be achieved by incorporating multiple experimental datasets. A more extensive range of experimental data would provide a broader foundation for refining potential parameters, reducing uncertainties, and ultimately resulting in more accurate structural models.
- **Supercomputing Capabilities:** Given the computational intensity of MD simulations and RMC refinements, accessing advanced supercomputing resources could significantly enhance the efficiency and scope of these studies. Collaborations with high-performance computing centers or cloud computing

platforms could offer the computational power needed for more intricate simulations and refinements.

- **Tailoring Potential Parameters:** Instead of relying solely on pre-existing potential parameter libraries, a more customized approach involving the generation of potential parameters specific to the studied glass composition could be explored. This entails fitting potential parameters to experimental data, creating a tailored set of parameters for improved accuracy.
- **Multidisciplinary Collaboration:** Bridging the expertise from diverse scientific disciplines, including materials science, computational chemistry, and machine learning, can lead to innovative methodologies and a more holistic understanding of glassy systems. Collaborative efforts could unlock novel insights and accelerate progress in this intricate field.
- **Exploration of Other Glass Systems:** While this study has focused on manganese lithium borate glass, extending these techniques to investigate a broader range of glass systems, including different metal borate compositions or variations in dopants, would contribute to a more comprehensive understanding of the structure-property relationships in glasses.
- **Validation and Benchmarking:** Continuous efforts to validate the accuracy of MD-RMC simulations against other experimental techniques and benchmarking against well-established glass systems could further establish the reliability of these simulation methods. This iterative validation process ensures the continuous improvement of the simulation models.

In summary, these suggestions aim to propel the field of glass structure studies forward, fostering innovation, efficiency, and accuracy in obtaining detailed insights into the atomic-level structures and properties of glassy materials. The iterative refinement of techniques and methodologies, coupled with interdisciplinary collaborations, promises exciting developments in the broader field of materials science.
