อาจารย์ที่ปรึกษา : อาจารย์ ดร. อัมพรรค์ วรรณโกมล, 165 หน้า.

ความดันภายในช่องว่างของเนื้อหินนั้นสัมพันธ์กับแรงกดทับของตัวหิน ซึ่งสามารถ
คำนวณได้จากค่าความเร็วของคลื่นตามยาวจากข้อมูลการสำรวจคลื่นไหวสะเทือน การศึกษานี้มี
วัตถุประสงค์เพื่อคาดการณ์ความดันของชั้นหินในแอ่งฝาง จังหวัดเชียงใหม่ ประเทศไทย โดยใช้
ข้อมูลจากการสำรวจคลื่นไหวสะเทือน ขั้นตอนการศึกษาหลักของการศึกษานี้คือ 1.) การรวบรวม
ข้อมูลที่เกี่ยวข้อง ประกอบด้วย ข้อมูลเวลาที่ใช้ในการเดินทางผ่านชั้นหินของคลื่นเสียง ข้อมูล
ความดันอันเนื่องมาจากน้ำหนักกดทับด้านบน และข้อมูลความดันของของไหลในหลุมเจาะ ของ
แหล่งน้ำมันสันทราย ซึ่งอยู่ในแอ่งฝาง 2.) การสร้างเส้นแนวโน้มของการอัดตัวปกติของชั้นหิน
จากข้อมูลเวลาที่ใช้ในการเดินทางผ่านชั้นหินของคลื่นเสียง ซึ่งได้จากการสำรวจคลื่นไหวสะเทือน
และ 3.) การคาดการณ์ความดันของชั้นหินโดยใช้วิธีของอีตัน ผลที่ได้จากการคำนวณหาความดัน
ภายในช่องว่างของเนื้อหินพบว่า ค่าความดันภายในช่องว่างของเนื้อหินต่อความลึกของพื้นที่ศึกษา
อยู่ในช่วงระหว่าง 0.434 ถึง 0.452 ปอนด์/ตารางนิ้ว/ฟุต และค่าความคลาดเคลื่อนเฉลี่ยของการ
คำนวณด้วยวิธีนี้ เมื่อคิดเป็นเปอร์เซ็นต์เฉลี่ยอยู่ที่ 1.24 ถึง 4.87 เปอร์เซ็นต์ ซึ่งข้อมูลการคาดการณ์
ความดันชั้นหินที่ได้จากการศึกษานี้สามารถนำไปใช้อ้างอิงสำหรับการวางแผนการขุดเจาะใน
บริเวณพื้นที่แอ่งฝางในอนาคตได้ต่อไป

BY SEISMIC DATA IN SAN SAI OILFIELD, FANG BASIN.

THESIS ADVISOR : AKKHAPUN WANNAKOMOL, Ph.D., 165 pp.

PORE PRESSURE PREDICTION/SEISMIC DATA/SAN SAI OILFIELD/FANG BASIN

Pore pressure is related to the stress of formation which can be calculated by compressional wave velocity from seismic exploration data. The objective of this study is to predict formation pore pressure in San Sai oilfield, Fang basin, located in Chiang Mai Province, Northern Thailand, by using seismic data. The main activities in this study are: (1) required data collecting, including seismic travel time data, overburden pressure data and hydrostatic pressure of San Sai oilfield located in Fang basin, (2) normal compaction trend generating from p-wave transit time, and (3) formation pore pressure predicting by using the Eaton's method of pressure prediction. Result from calculated pore pressure indicated that pore pressure gradient in study area is in range between 0.434 and 0.452 psi/ft and erroneous percentage of this method is in range between 1.24% and 4.87%. Thus the predicted formation pore pressure data that obtained from this study will be informatively supported for drilling plan in Fang basin in the future.

ACKNOWLEDGEMENTS

The author would like to express my sincere thanks to my thesis advisor, Dr. Akkhapun Wannakomol for his consistent supervision, guiding, and support throughout this research. I am most grateful for his teaching and advice. I would not have achieved this far and this thesis would not been completed without all of supported that I have always received from him.

My thanks go to Assoc. Prof. Kriangkrai Trisarn and Dr. Chongpan Chonglakmani for their valuable suggestion and guidance given as committee members.

The author is also grateful to all the faculty and staff members of the School of Geotechnology and colleagues for their help and assistance throughout the period of this work.

The author wishes to thanks Northern Petroleum Development Center, Defence Energy Department, Defence Industry & Energy Center and their staff for supporting seismic, well logging, and geological data and also thank you for their service and accommodate me throughout the data collecting period.

Finally, I would also like to express my deep sense of gratitude to my parents for their support and encouragement me throughout the course of this study at the Suranaree University of Technology.

CHAPTER I

INTRODUCTION

1.1 Rationale and background

Pore pressure is defined as the fluid pressure in the pore space of the rock matrix. In a geologic setting with perfect communication between the pores, the pore pressure is the hydrostatic pressure due to the weight of the fluid. Hydrostatic pressure is often referred to normal pressure conditions. Conditions that deviate from normal pressure are said to be either overpressured or underpressured, depending on whether the pore pressure is greater than or less than the normal pressure. The term “geopressure” is often used to describe abnormally high pore fluid pressures. Knowledge of the pore pressure in an area is important for several reasons. In overpressured zones, there is often little difference between the fluid pressure and the reservoir fracture pressure. In order to maintain a safe and controlled drilling, the mud weight must lie in this interval (i.e. between fluid pressure and fracture pressure). If a too low mud weight is used (underbalanced drilling) while drilling through high pressure zones, well kick is normally occurred and it is danger. In rare cases one might encounter dangerous blowouts, although the risk of this is significantly reduced during the last decade thanks to modern equipment. If the mud weight is too high, the formation fracture pressure is exceeded, and the drill pipe may be stuck. In either case, valuable operation time is lost.

1.2 Research objective

The objective of this thesis is to calculate pore pressure gradient by using seismic data which had been run in Fang basin, Chiang Mai Province (Figure 1.1). The result from this study can be used for pore pressure predicting and apply to the drilling program for new well drilling in the study area.

1.3 Scope and limitation of the study

The Scope and limitations of this thesis are listed as follows;

- 1.3.1 The data used in this thesis based only on seismic data run in Fang basin.
- 1.3.2 A calculated pore pressure can specifically predict pore pressure gradient only in Fang basin.
- 1.3.3 Due to limitation in sonic velocity data available, calculated pore pressure can predicted only on the normal pressure trend.

Figure 1.1 Location of study area in Fang basin, Chiang Mai, Thailand

CHAPTER II

LITERATURE REVIEW

2.1 Pore pressure

Pore pressure is defined as the fluid pressure in the pore space of the rock matrix. In a geologic setting with perfect communication between the pores, the pore pressure is the hydrostatic pressure due to the weight of the fluid. The pore pressure at depth z can then be computed as (Bourgoyne *et al.*, 1986):

$$p(z) = \int_{z_0}^z \rho(z)gzdz + p_0 \quad (2.1)$$

where $\rho(z)$ = fluid density (lbm/gal),

g = gravitational acceleration (ft/s²)

p_0 = pressure at depth z_0 , usually atmospheric pressure (psi).

Hydrostatic pressure is often referred to as normal pressure conditions. Conditions that deviate from normal pressure are said to be either overpressured or underpressured, depending on whether the pore pressure is greater than or less than the normal pressure. The term “geopressure” is often used to describe abnormally high pore fluid pressures.

The concept of abnormal pressure, especially geopressure, is most important in hydrocarbon exploration and production. Drilling through geopressure zones is

challenging, and requires extra care. As fields have matured, there is a rising demand in the industry to explore areas that previously were regarded as too technically challenging. This includes deepwater areas, which are often associated with high pore pressures. Dutta (2002b) reports that the industry will spend about \$100 billion in hydrocarbon exploration and production in deepwater areas over a five-year period, beginning in 2001. In the North sea it is estimated that each deep-drilled well (high-temperature, high-pressure well) on average gives 2 kicks related to high pore pressures.

Figure 2.1 Pore space in sandstone (blue color) (Øyvind Kvam, 2005)

High pore pressures have been observed at drilling sites all over the world, both on- and offshore. The frequently encountered overpressures in the Gulf of Mexico have been particularly well studied and observed, since this is an important area of hydrocarbon production, but the phenomenon have been observed in many other places, including the North Sea, the Caspian Sea, Pakistan and the Middle East

(Fertl, 1976). The nature and origin of pore pressures are manifold and complex. The demands for better understanding and pre-drill prediction of pore pressure are substantial. The industry spends considerable sums on research, and the efforts have paid off.

In order to investigate the nature of abnormal pore pressures some practical definitions have been made. The overburden pressure is defined as the combined weight of sediments and fluid overlying a formation. Mathematically, the overburden pressure can be defined as (Bourgoyne *et al.*, 1986):

$$S(z) = \int_{z_0}^z \rho(z) g dz \quad (2.2)$$

and

$$\rho(z) = \phi(z) \rho_f(z) + (1 - \phi(z)) \rho_m(z) \quad (2.3)$$

where ϕ = porosity,
 ρ_f = fluid density (lbm/gal)
 ρ_m = rock matrix density (lbm/gal).

If the density is known, the overburden pressure can be measured.

The effective pressure is defined as (Fjær, *et al.*, 1989):

$$P_e = S - nP \quad (2.4)$$

where P_e = effective pressure (psi),
 P = pore fluid pressure (psi)
 n = Biot coefficient.

For static compression of the rock frame, the Biot coefficient is defined as (Fjær, *et al.*, 1989):

$$n = 1 - \frac{K_{fs}}{K_s} \quad (2.5)$$

where K_{fs} is the bulk modulus of the rock frame (psi) and K_s is the bulk modulus of the mineral that the rock is composed of (psi). For soft materials, $n = 1$

It is also convenient to define the pressure gradient G , which strictly speaking is not really a gradient, but an engineering term. The pressure gradient is simply defined as the ratio of pressure to depth. Pressure gradients can describe overburden, fluid and effective pressures. As an example, in the Gulf of Mexico, the overburden gradient is found to be very close to 1 psi/ft, while normal pressure conditions (i.e. hydrostatic pressure) correspond to a fluid pressure gradient of about 0.465 psi/ft (Dutta, 1987).

From the definitions above it is clear that a high pore pressure will give a correspondingly low effective pressure. The degree of overpressure may in extreme cases be such that the effective pressure equals zero, and in some rare cases even is less than zero. Table 2.1 summarizes degrees of pressures encountered based on experience from the Gulf of Mexico, as given in Dutta (1987).

Table 2.1 Geopressure characterization according to Dutta (1987).

Fluid pressure gradient (Psi/ft)	Geopressure characterization
$0.465 < G < 0.65$	soft or mild
$0.65 < G < 0.85$	intermediate or moderate
$G > 0.85$	hard

According to Fertl (1976) all occurrences of overpressure in the subsurface are associated with a permeability barrier that simultaneously acts as a pressure barrier. This barrier prevents fluid to flow along a pressure gradient. The nature of such a seal can differ greatly at different localities. Low permeability shales have often been observed to act as pressure barriers, but also faults can form such barriers.

The processes in which high pressures develop in the vicinity of the pressure barriers are complex. Smith (1971) described how high pressures can develop in areas where there have been rapid depositions of sediments, allowing seals to form before excess fluid has escaped from deeper layers. The increasing weight of the overburden will tend to decrease the porosity, and hence the pore space. However, if the formation is sealed, the fluid has nowhere to escape and starts to carry some of the weight of the overburden. The result is that the fluid pressure is increased. This process is often termed “undercompaction” or “compaction disequilibrium”, and is one of the major causes of abnormally high pore pressures (Dutta, 2002).

Tectonic activity may also cause high pressures. Physical deformation of geological formations may for instance change the volume in which the sealed-off pore fluid exists, thus changing the pressure. Salt diapirism is an example of physical deformation of the subsurface. Areas where salt tectonism is frequent are often associated with high pore pressures (e.g., Gulf of Mexico).

2.2 Pore pressure prediction strategies

Bourgoyne *et al.* (1986) clearly summarized four mechanisms for generating abnormal pore pressures, or overpressures; Compaction, Diagenesis, Differential Density and Fluid Migration. The most common overpressure generating mechanism is compaction. When sediments are deposited in a deltaic depositional environment (the most common depositional environment) the sediments are initially unconsolidated and remain in suspension with the carrying fluid, typically sea water. As the depositional process continues, the sediments come into contact with each other and are able to support the weight of the sediments being deposited above them by the grain-to-grain contact points. Throughout this process, the formation continues to remain in hydraulic communication with the fluid source above. As the depositional process continues, the weight of the overlying sediments begins to compact the sediments, causing the sediments to realign, resulting in a reduced porosity and expulsion of fluid from the formation. As long as the pore fluid can escape as quickly as required by the natural compaction process, the formation pore space will remain in hydraulic communication with the fluid source and the pore pressure is solely the hydrostatic pressure generated from the density of the pore fluid. However, if the natural compaction process is faster than the rate of the pore fluid expulsion, abnormal formation pressures will be generated due to some of the load being placed upon the sediments being supported by the pressure in the pore fluids.

The second overpressure generating mechanism explained by Bourgoyne *et al.* is diagenesis. Diagenesis is defined as the physical, chemical or biological alteration of sediments into sedimentary rock at relatively low temperatures and pressures that

can result in changes to the rock's original mineralogy and texture. It includes compaction, cementation, recrystallization, and perhaps replacement, as in the development of dolomite. In Gulf of Mexico sedimentary basins, one diagenetic process is the conversion of montmorillonite clays to illites, chlorites and kaolinite clays during compaction when in presence of potassium ions. Water is present in clay deposits as both free water and bound water. The bound water has significantly higher density. During diagenesis, as the bound water becomes free water, the higher density bound water must undergo a volume increase as it desorbs. If the free water is not allowed to escape (i.e. rapid compaction, precipitates caused from diagenesis, caprock, etc.), then the pore pressure will become abnormally pressured. Diagenesis typically occurs under bottomhole temperatures of at least 200 °F.

The third overpressure generating mechanism described by Bourgoyne *et al* is differential density. This mechanism occurs when a formation contains a pore fluid with a density significantly less than the normal pore fluid density for the area. If the structure has significant dip, then the extension of the structure up dip will result in higher pore pressure gradients than experienced down dip where the pressure gradient is known. Although the up dip pore pressure will be lower in absolute pressure, the pressure gradient will be higher requiring a higher hydrostatic gradient to control the pore pressure.

The fourth and final overpressure generation mechanism elucidated by Bourgoyne *et al* is fluid migration. This mechanism occurs when overpressured formations have a communication path to a normally pressured formation and the normally pressure formation becomes charged. The hydraulic communication path can be man-made or naturally occurring.

Karl Terzaghi (1943) developed a simple relationship between pore pressure and the effective stress of the rock. Even though his relationship was determined empirically, it was proven later that it can be derived analytically from 1-D compaction theory. Terzaghi noted: The stresses in any point of a section through a mass of soil can be computed from the total principal stresses $\sigma_1, \sigma_2, \sigma_3$, which act in this point. If the voids of the soil are filled with water under a stress μ , the total principal stress consists of two parts. One part, μ , acts in the water and in the solid in every direction with equal intensity. It is called the neutral stress (or the porewater pressure). The balance $\sigma_i = \sigma_i - \mu$ represents an excess over the neutral stress μ , and it has its seat exclusively in the solid phase of the soil. This fraction of the principal stress will be called the effective principal stress. A change in the neutral stress μ produces practically no volume change and has practically no influence on the stress conditions for failure. Porous materials (such as sand, clay and concrete) react to a change of μ as if they were incompressible and as if their internal friction were equal to zero. All the measurable effects of a change of stress, such as compression, distortion and a change of shearing resistance are exclusively due to changes in the effective stress σ'_i .

The above statement indicates that this is a conceptual stress. Only the effects of an effective stress change are measurable, not the effective stress itself. Terzaghi determined the following mathematical relationship: $\sigma_{ei} = \sigma_i - P_f$.

where P_f is the formation pressure (psi), σ_i is the principal stress (psi) and σ_{ei} is the effective vertical stress (psi)

Therefore, pore pressure can be calculated from the difference between principal and effective stresses acting in a given direction. In the case of drilling for oil and gas, the principal stress in the vertical direction is the overburden stress, which can be determined by a number of published correlations or by integration of the bulk density log data. The unknown variable is the corresponding conceptual effective stress. In general, overpressuring during the compaction process is associated with a slower porosity decrease with depth. If the assumption is made that vertical strains dominate during the compaction process, then Terzaghi's principle would imply that the effective vertical stress is the exclusive cause of shale porosity variations. Therefore, pore pressure is determined from the effective vertical stress and the overburden stress by the following relationship (Terzaghi, 1943):

$$P_f = \sigma_{OB} - \sigma_{EV} \quad (2.6)$$

where P_f = formation pressure (psi)

σ_{OB} = overburden stress (psi)

σ_{EV} = effective vertical stress (psi)

One of the early papers published on pore pressure interpretation was authored by Hottman and Johnson. The authors included a description of the pore pressure, overburden stress and effective vertical stress relationship described by Terzaghi. They recognized the significance of Terzaghi's relationship and developed an empirical relationship between fluid pressure gradient (FPG) and the electrical log properties. The data sets used for the development of the techniques were taken from Tertiary sediments located in Southern Louisiana and the Upper

Texas Gulf Coast. The geologic age of the acquired data set was Miocene and Oligocene.

The pore pressure and acoustic data used in the interpretation technique is included in Table 2.2.

Table 2.2 Pressure and acoustic log data – overpressured Miocene-Oligocene

Formations, South Louisiana and Upper Texas Gulf Coast per Hottman and Johnson.

Data presented in Table 2.2 was plotted and showed in Figure 2.2. Figure 2.2 illustrates the relationship of the difference between the interval transit time of the observed shale and the interval transit time of the normally pressured shale section ($dT_{ob(sh)} - dT_{n(sh)}$) values and Formation Pressure Gradient (FPG).

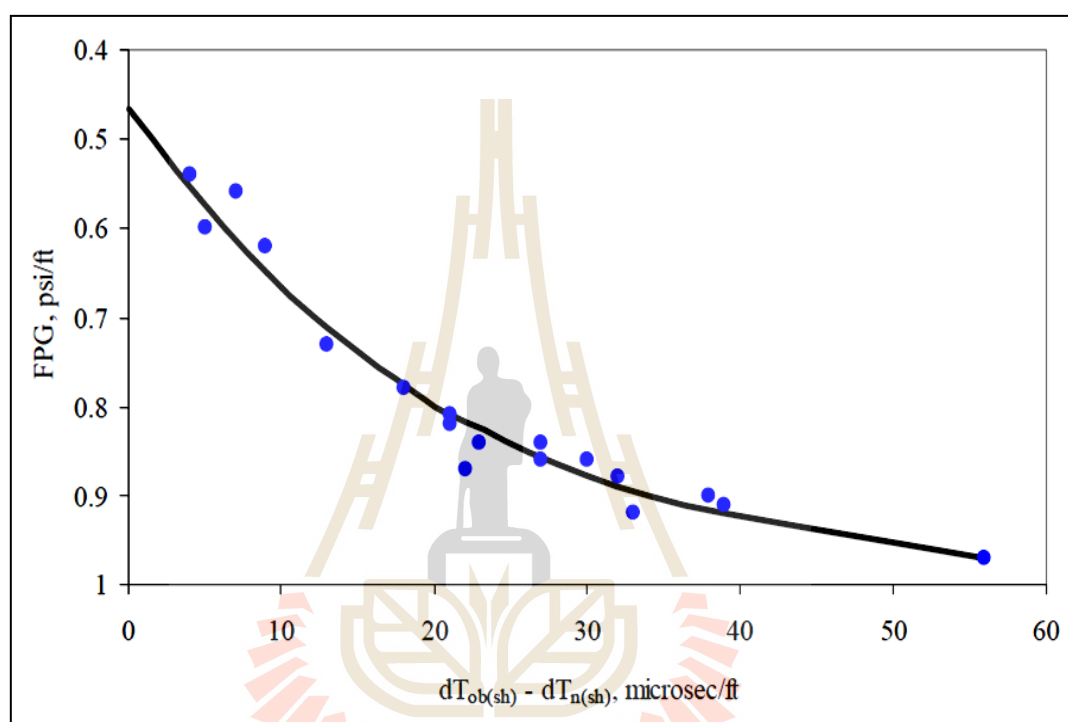

Figure 2.2 Relationship between shale acoustic parameter $dT_{ob(sh)} - dT_{n(sh)}$ and reservoir FPG per Hottman and Johnson

To estimate pore pressure the following procedures had been developed when acoustic travel time data were known for shale formations.

1. The “normal compaction trend” for the area of interest is established by plotting the logarithm of $dT_{(sh)}$ vs. depth as showed in figure 2.3.
2. A similar plot is made for the well in question.

3. The top of the overpressured formation is found by noting the depth at which the plotted points diverge from the trendline.
4. The fluid pressure gradient of a reservoir at any depth is found as follows:
 - 4.1 The divergence of adjacent shales from the extrapolated normal line is measured.
 - 4.2 The fluid pressure gradient (FPG) corresponding to the $(dT_{ob(sh)} - dT_{n(sh)})$ value is found using the solid black line in Figure 2.2.
5. The FPG value is multiplied by the depth to obtain reservoir pressure.

Figure 2.3 Shale travel time vs burial depth for Miocene and Oligocene Shales, South Louisiana and Upper Texas Gulf Coast per Hottman and Johnson

In 1972 Eaton published a technique for pore pressure prediction. Eaton recognized that Hottman and Johnson's basic relationship is correct, but can be improved. Hottman and Johnson's relationships, in the simplest terms, are as follows:

$$P_f / D = f(dT_{ob(sh)} - dT_{n(sh)}) \quad (2.7)$$

where P_f = formation pore pressure (psi)

D = depth (ft)

$dT_{ob(sh)}$ = observed shale transit time (millisecond)

$dT_{n(sh)}$ = normal shale transit time (millisecond), obtained from normal compaction trend

After rearrangement of the terms, the relationships are as follows:

$$\frac{dT_{ob(sh)}}{dT_{n(sh)}} = f(P_f / D) \quad (2.8)$$

Though Hottman and Johnson recognized Terzaghi's relationship to be true, their relationship did not follow the same form. Specifically, there was no way to distinguish the effects of the three variables in Terzaghi's pore pressure relationship. Their relationship related pore pressure to just one petrophysical parameter, whether it was formation resistivity or interval transit time.

Eaton noted that the technique developed by Hottman and Johnson utilized just a single line drawn through the FPG versus the petrophysical parameter data and that data was considerably scattered. This led Eaton to expand on Hottman and Johnson's relationships. Eaton combined Terzaghi's and Hottman and Johnson's relationships by solving Terzaghi's relationship for pressure and dividing all of the variables by depth as follows:

$$\frac{P_f}{D} = \left(\left(\frac{\sigma_{OB}}{D} \right) - \left(\frac{\sigma_{EV}}{D} \right) \right) \quad (2.9)$$

where σ_{OB} = overburden stress (psi)

σ_{EV} = effective vertical stress (psi)

Eaton postulates that the parameters derived from petrophysical log data are dependent variables primarily controlled by the pore pressure gradient and overburden stress gradient groups. He believed that Hottman and Johnson's relationships should be expanded to account for the effect of the overburden stress gradient. Up to this point, it was argued that the overburden stress gradient is constant for a given area and of no significance. Eaton refutes this argument saying that overburden stress gradients are functions of burial depth in areas where compaction and abnormal pressures are caused by increasing overburden loads with deeper burial. The overburden stress is a function of burial depth and formation bulk density by the following relationship:

$$\sigma_{ob} = \int \rho_b dD \quad (2.10)$$

where ρ_b is the formation bulk density (lbm/gal)

Eaton (1972) presented a mathematical expression which related sonic travel times to pore pressure. Reynolds (1970) described how velocities derived from seismic data could be used for pore pressure prediction. All methods take advantage of the fact that sonic velocities depend on the effective pressure, and hence the pore pressure.

Travel time and pore pressure relationship proposed by Ben Eaton (1972):

$$P_{pore} = OB_Z - [OB_Z - Pn_Z] \times \left(\frac{\Delta t_n}{\Delta t_o} \right)^\alpha \quad (2.11)$$

- where P_{pore} = Predicted pore pressure (psi)
- OB = Overburden pressure (psi)
- Pn = Normal pressure (psi)
- Z = Depth to point of measurement (ft)
- Δt_n = The assumed normal sonic slowness at depth Z calculated from the Normal compaction trend line ($\mu\text{sec}/\text{ft}$)
- Δt_o = The observed (measured) sonic slowness at depth Z ($\mu\text{sec}/\text{ft}$)
- α = Pore Pressure transformation exponent variable with age/basin location (no unit),

The relationship between effective pressure and velocity depend heavily on the texture and mineral composition of the rock. For instance, for unconsolidated sandstones, the P-wave velocity varies significantly with effective pressure (Domenico, 1977). The mechanism thought to be important here is the strengthening of grain contacts with increasing effective pressure. When applying external load to unconsolidated sand, the contacts between the individual grains become stronger. Thus the stiffness of the sand is increased. This leads to an increased P-wave velocity (Mindlin and Deresiewicz, 1953). On the other hand, velocities in consolidated rocks may also vary significantly with pressure. This is not due to strengthening of grain contacts, but rather to microscopic cracks in the rock. When applying external pressure, these cracks tend to close, thus creating contacts at the crack surfaces. As a

result, the P-wave velocity increases. However, for consolidated rocks with little cracks, the velocities may not vary very much with pressure. In fact it can be shown (Dvorkin, *et al.*, 1991) that the granular rock with cemented grain contacts have no pressure dependence at all.

The cause of geopressuring may be significant for discriminating between normal and high pore pressure based on seismic velocities. In the previous section, undercompaction was mentioned as one of the most important geological processes for buildup of abnormally high pore pressures. A consequence of undercompaction is that the porosity of the sediments is preserved. This means that undercompacted sediments are more porous than compacted sediments. The porosity is one of the key factors determining the velocity of a rock. Both theoretical considerations and experiments show that seismic velocities in general decrease with increasing porosity. Thus, undercompacted sediments tend to have lower velocities than compacted sediments. In cases where the cause of geopressuring is due to other geological processes, the porosity does not have to be abnormally high. However, the mechanisms mentioned above (contact stiffness and microcracks) may still influence the velocity.

2.3 Fang basin

2.3.1 General geology of Fang basin

Fang Basin is a NNE-SSW trending, small intracratonic basin. It formed in the Early Tertiary and evolved in the Middle Tertiary in a transtensional regime followed by Pliocene to Pleistocene compression in a transtensional /transpressional left-lateral tectonic system (Zollner and Moller, 1996). The

depositional environment in the Tertiary was fluvial-lacustrine and changed to fluvial and alluvial in the Quaternary (Settakul, 1985). It is on the western margin of the Sokhothai fold belt, which comprises Paleozoic and Triassic strata and volcanic rocks that accumulated on the eastern margin of the Shan-Thai craton prior to the Indosinian orogeny. This fold belt is complex and deformed by granitic intrusions during the collision of the Indochina and Shan-Thai cratons (Bunopas and Vella, 1983).

2.3.2 Structure of Fang basin

Fang basin is a half-graben that has a steep faulted western flank and a gently dipping eastern flank. The basin can be divided in three sub-basins. These are Huai Pasang, Huai Ngu, and Pa Ngew sub-basins, the three being separated by saddles formed by older rocks. The deepest part of Fang basin is the central Huai Ngu sub-basin, which has a sedimentary fill of 3,000 m (Settakul, 1985). Fang basin now produces oil from five structures, all of which are in the Huai Ngu sub-basin. The order of oil production, from high to low, is the Mae Soon, San Sai, Nong Yao, Ban Thi, and Sam Jang structures.

2.3.3 Stratigraphy and sedimentological overview of Fang basin

The Pre-Tertiary basement rocks consist of sedimentary, metamorphic and igneous rocks. On the western side of the basin, the rocks are Cambrian-Permian in age, and include Carboniferous granite. On the eastern side of the basin, the rocks are Silurian-Devonian and Jurassic, with Triassic granite. The Tertiary rocks of the Fang basin are conglomerate, sandstone, claystone and shale. The Quaternary deposits are silt, clay, sand and gravel and occur as stream channels, terrace deposits and alluvial fans. These sediments are covered by recent soil and lateritic sand.

Figure 2.4 Stratigraphy of the Fang basin (modified after Buravas (1973); Sethakul (1984); Settakul (1985))

2.3.4 Petroleum system of the Fang basin

Zollner and Moller (1996) described the hydrocarbon system of Fang basin and suggested that the source rocks were deposited in a lacustrine environment. Potential source rocks include bituminous shale and lignite of the Lower Mae Sod formation. Reservoir rocks in the Mae Soon and the San Sai structures are infill sands of the Upper Mae Sod formation, whereas in the Pong Nok area they are westward prograding sandstone that pinches out towards the east. Mostly intra-formation shale layers are interpreted to act as seals. The generation of structures was related to the compression during the Pliocene to Pleistocene. Source rocks were within the oil window during this time. Top of the oil window is interpreted to be located at a depth of approximately 2,750 ft (Temperature gradient: 7.2 °C / 100 m). Migration pathways are interpreted to have been updip and along faults.

CHAPTER III

RESEARCH METHODOLOGY

Prediction of pore pressure within study area had been conducted by using seismic velocities. The steps that used to calculate pore pressure in this research are:

1.) Seismic data collecting and preparing, 2.) Normal compaction trend generating, and 3.) Pore pressure calculation

3.1 Seismic data collecting and preparing

Seismic data from eight 2D Seismic lines including Line S-2, Line S-3, Line F-89-031, Line F-1, Line F-2, Line F-3, Line F-89-038 and Line F-89-040 were collected and analyzed to calculate pore pressure gradient. Location of studied seismic survey lines are presented in Figure 3.1. All of seismic lines had to prepare in to time – depth relationship form by using Dix's equation as showed below:

$$h_n = \frac{V_n (t_{0(n)} - t_{0(n-1)})}{2} \quad (3.1)$$

where h_n = thickness of layer n (ft)

V_n = Interval velocity at laver n (ft/sec)

$t_{0(n),(n-1)}$ = zero offset reflection time at reflector n and $n-1$ respectively
(sec)

and

$$H_n = \sum_1^n h_i \tag{3.2}$$

where H_n is depth to layer n (ft)

Figure 3.1 Location of studied seismic survey lines and reference well
FA-SS-37-07 (green) and well FA-SS-37-08 (blue)

3.2 Normal compaction trend generating

Normal compaction trend can be generated by making a transit time–depth plot on semi-log paper. The normal compaction trend can be determined by drawing a straight line through the average of transit time value in the relative depth.

In this research twenty four of normal compaction trend lines were created, three data sets from each seismic line were used to create normal compaction trend lines.

3.3 Pore pressure calculation

The pore pressure had been calculated from travel time and pore pressure relationship proposed by Ben Eaton (1972) in equation 2.11:

$$P_{pore} = OB_z - [OB_z - Pn_z] \times \left(\frac{\Delta t_n}{\Delta t_o} \right)^\alpha \quad (2.11)$$

where OB = Overburden pressure at depth z (psi)

Pn = Normal pressure at depth z (psi)

According to the theory, overburden pressure gradient and normal pressure gradient (hydrostatic pressure gradient) that used in this research were set as 1 psi/ft and 0.433 psi/ft respectively and used pore pressure transformation exponent variable(α) as 0.3 (This value was obtained from fitting curve between RFT and sonic log data from well FA-SS-37-08).

Therefore, equation 2.11 had been transformed to:

$$P_{pore_z} = (1 \times D_z) - [(1 \times D_z) - (0.433 \times D_z)] \times \left(\frac{\Delta t_n}{\Delta t_o} \right)^{0.3} \quad (3.3)$$

where D = depth at interesting depth z (ft)

α = 0.3 (This value obtained from filling curve between RFT and sonic log data of well FA-SS-37-08)

In this study, Equation 3.3 had been used to calculate the pore pressure throughout the study.

In order to check the accuracy of the calculated pore pressure from this study, pressure data obtained from Repeat Formation Test (RFT) of well FA-SS-37-08 and from deriving from pressure gradient of well FA-SS-37-07 were used for comparison. Locations of well FA-SS-37-07 and well FA-SS-37-08 are depicted in Figure 3.1.

CHAPTER IV

RESULTS AND DISCUSSION

In order to study the relationship among pore pressure, depth, and seismic wave travel time, these data were each other cross-plotted and some results can be summarized as follows.

4.1 Normal compaction trend lines

Normal compaction trend lines were generated from plotting transit time versus depth in semi-logarithmic scale and generated trend lines by using Microsoft Excel 2010.

Normal compaction trend lines of first data set which were collected from shot point numbers closed to reference drilling well (well FA-SS-37-07 and FA-SS-37-08) including Line S-2 SPN 1560, Line S-3 SPN 1476, Line F-89-031 SPN 1257, Line F-1 SPN 1231, Line F-2 SPN 1227, Line F-3 SPN 1266, Line F-89-038 SPN 1127, and Line F-89-040 SPN 1131 are showed in Figure 4.1 – Figure 4.8.

Normal compaction trend lines of second data set which were located next to the first data set, including Line S-2 SPN 1524, Line S-3 SPN 1440, Line F-89-031 SPN 1189, Line F-1 SPN 1174, Line F-2 SPN 1192, Line F-3 SPN 1228, Line F-89-038 SPN 1079, and Line F-89-040 SPN 1085 were results in Figure 4.9 – Figure 4.16.

Normal compaction trend lines of third data set which were located next to the first data in the opposite side of second data set including Line S-2 SPN 1596, Line S-3 SPN 1512, Line F-89-031 SPN 1313, Line F-1 SPN 1286, Line F-2 SPN

1271, Line F-3 SPN NULL, Line F-89-038 SPN 1127, and Line F-89-040 SPN 1167 were results in Figure 4.17 – Figure 4.24.

4.2 Pore pressure calculation

Pore pressure were calculated after normal compaction travel time had been calculated and known from the previous section. Microsoft Excel 2010 was then used to calculated pore pressure by using equation 3.3.

Resulted pore pressure of the first data set including Line S-2 SPN 1560, Line S-3 SPN 1476, Line F-89-031 SPN 1257, Line F-1 SPN 1231, Line F-2 SPN 1227, Line F-3 SPN 1266, Line F-89-038 SPN 1127, and Line F-89-040 SPN 1131 compared with pressure data from Repeat Formation Test (RFT) of well FA-SS-37-08 and from the pressure gradient of well FA-SS-37-07 (depth in between 2,238 and 4,625 ft) are showed in Figure 4.25 – Figure 4.32.

Resulted pore pressure of the second data set including Line S-2 SPN 1524, Line S-3 SPN 1440, Line F-89-031 SPN 1189, Line F-1 SPN 1174, Line F-2 SPN 1192, Line F-3 SPN 1228, Line F-89-038 SPN 1079, and Line F-89-040 SPN 1085 compared with RFT pressure data of well FA-SS-37-08 and from the pressure gradient of well FA-SS-37-07 (depth in between 2,238 and 4,625 ft) are showed in Figure 4.33 – Figure 4.40.

Resulted pore pressure of the second data set including Line S-2 SPN 1596, Line S-3 SPN 1512, Line F-89-031 SPN 1313, Line F-1 SPN 1286, Line F-2 SPN 1271, Line F-3 SPN NULL, Line F-89-038 SPN 1192, and Line F-89-040 SPN 1167 compared with RFT pressure data of well FA-SS-37-08 and from the pressure gradient of well FA-SS-37-07 (depth in between 2,238 and 4,625 ft) are showed in Figure 4.41 – Figure 4.48.

Figure 4.48 Pore pressure calculated from seismic line F-89-040 shot point number 1167 data

According to result of three data sets plotting above, it showed that the pressure trend is coincident with the reference pressure. This may imply that the study area that covered with used shot point numbers in every data set, especially in depth between 2238 and 4625 ft, is in normal pressure zone and its geological characteristic is similar to well FA-SS-37-08 and FA-SS-37-07.

After considering all graphs, some information can be pointed out as follows;

- 1.) At the beginning of graph, calculated pore pressure tends to high this because that depth is in Mae Fang formation which is semi-consolidated rock. In general, semi-consolidated rock usually has high porosity and high fluid content. This causes P-wave transit time increase and resulted in calculated pore pressure increasing.
- 2.) Some data of line S-3 are not followed the trend; this probably due to line S-3 may be lain near the fault and some parts of line S-3, especially shot point number 1440 were lain through that fault, this could cause slightly in P-wave velocity and in calculated pore pressure distortion.

4.3 Efficiency testing

In this part, calculated pore pressures derived from this study were tested for check its accuracy by compared with the reference pressure which was recorded from RFT data of well FA-SS-37-08 and by converted from pressure gradient of well FA-SS-37-07.

The reference pressure was re-scale by extrapolated it in to calculated pressure scale then erroneous percentage was calculated from following equation:

$$\left(\frac{P_c - P_r}{P_r} \right) \times 100 \quad (4.1)$$

where P_c is calculated pore pressure (psi) and P_r is reference pressure (psi)

The following figures and tables show the comparison of calculated pressure and reference pressure of the first data set, including Line S-2 SPN 1560, Line S-3 SPN 1476, Line F-89-031 SPN 1257, Line F-1 SPN 1231, Line F-2 SPN 1227, Line F-3 SPN 1266, Line F-89-038 SPN 1127, and Line F-89-040 SPN 1131, respectively.

Efficiency and accuracy of this method was displayed in erroneous percentage. From results above, maximum average error is 4.87 % whilst minimum average number is 1.24%. In general, these values are acceptable. This may prove and assure that prediction of pore pressure by using seismic data can use confidently in Fang basin.

CHAPTER V

CONCLUSION AND RECOMMENDATION

5.1 Conclusions

Pore pressure prediction by using seismic data based on Eaton's formula for pore pressure prediction and applied pore pressure transformation as 0.3 is applicable to San Sai oil field with acceptable accuracy. Number 0.3 was obtained from fitting graph between calculated pore pressure using sonic log from well FA-SS-37-08 and reference pressure obtained from RFT data at the same well.

Eaton's equation used to calculate pore pressure is

$$P_{pore} = OB_Z - [OB_Z - Pn_Z] \times \left(\frac{\Delta t_n}{\Delta t_o} \right)^\alpha$$

Therefore, in this study this equation was then modified to:

$$P_{pore} = (1 \times Z) - [(1 \times Z) - (0.433 \times Z)] \times \left(\frac{\Delta t_n}{\Delta t_o} \right)^{0.3}$$

where P_{pore} = Predicted pore pressure (psi)

OB = Overburden pressure used 1 psi/ft

Pn = Normal pressure used 0.433 psi/ft

Z = Depth to point of measurement (ft)

- Δt_n = The assumed normal sonic slowness at depth Z calculated from the Normal compaction trend line ($\mu\text{sec}/\text{ft}$)
- Δt_o = The observed (measured) sonic slowness at depth Z (sec/ft)
- α = Pore Pressure transformation exponent variable with age/basin location

Before calculate pore pressure, normal compaction trend line had to first generated by plot transit slowness (Δt , $\mu\text{sec}/\text{ft}$) and depth (ft) on semi-logarithmic graph. Corresponding linear equation that obtained from each shot point number in normal compaction trend line generating are showed in Table 5.1.

Table 5.1 Corresponding linear equation obtained from each shot point which is used to calculated normal sonic slowness (Δt_n , $\mu\text{sec}/\text{ft}$)

Seismic Line	Shot point number	Equation

	1131	0.436
	1167	0.436

Efficiency and accuracy of this method was showed in erroneous percentage. The erroneous percentage of pore pressure calculated from this method in study area compared with pressure obtained from well FA-SS-37-08 is in range between 1.42% and 4.87% and compared with well FA-SS 37-07 is in range between 1.24% and 4.81%. In general, these values are acceptable. This may prove and assure that prediction of pore pressure by using seismic data can use confidently in Fang basin.

Dependability of this research is in range with in depth between 1000 and 5000 ft. These because at depth over 1000 ft, it is in Mae Fang formation which is unconsolidated formation, P wave velocity is slow and affected to increase in

calculated pore pressure. On the other hand at depth below 5000 ft. calculated pore pressure tends to increase because it reaches the basement.

However, this relationship can only be applied to Fang basin due to its data source and geological characters of the study area.

5.2 Recommendations

In case of having more formation transit time data which obtained from seismic data, recorded and/or calculated from RFT or other well logging tools, this will enable to detect the area or depth that pressure alter from the normal pressure, both abnormal pressure zone and subnormal pressure zone, as illustrated in Figure 5.1 which is plotted from relationship of Δt and depth. From Figure 5.1 it can be notified that abnormal pressure zone depicts transit time higher than normal trend line whilst subnormal pressure zone depicts transit time lower than normal trend line.

Figure 5.1 Relationships of transits time Δt and depth, that can be used for abnormal and subnormal pressure zone detection

5.3 Further study

For the future work, there are some recommendations as listed below:

1. Calculated pore pressure should be modified if there are more seismic or other sonic data collected in same area.
2. Other electric wireline logs, e.g. sonic log, resistivity log and density log or other drilling data may be tried in the same way to calculated pore pressure.

BIOGRAPHY

Mr. Adisorn Sridej was born on March 30, 1985 in Nakhon Sawan, Thailand.

He earned his Bachelor's Degree in Engineering in Petrochemical and polymeric materials from Silpakorn University in 2008. After that, he then continued his Master's degree in Geotechnology at School of Geotechnology, Institute of Engineering, Suranaree University of Technology. He interested in drilling engineering and formation evaluation.
