OIL RESERVOIR DISTRIBUTION MAP/ WIRELINE LOGGING/ MAE-SOON  
OIL FIELD

This study is aimed to analyze the quality and spatial distribution of the potential oil reservoirs of Mae-Soon oil file, Fang Basin, Chiang Mai province by using wireline logging data and Geographic Information Systems (GIS) as the tool for mapping and demonstrating the distribution of the potential oil reservoirs of Mae-Soon oil field. The results of the study revealed that there were oil sandstone reservoirs in Mae Sod Formation of Mae-Soon oil field. These sandstone reservoirs could be divided into 19 major sandstones layers which could be grouped into three groups as group A, group B and group C based on their gamma ray, spontaneous potential, and resistivity characteristics, respectively. Sandstone Group A has 2 potential hydrocarbon-bearing zones which are located in the north-western and south-western part of the field. Sandstone Group B has 3 potential hydrocarbon-bearing zones which are located in the north-western, eastern, and western part of the field, respectively. Sandstone Group C has 4 potential hydrocarbon-bearing zones which are located in the north-western, north-eastern, eastern, and south-western part of the field, respectively.

## **ACKNOWLEDGEMENTS**

Completion of this report would have been impossible without the interest and direct participation of a member of individuals to whom I owe everlasting gratitude sincere appreciation in extended to everyone who I worked in connection with this scholastic achievement.

In particular, I would like to acknowledge the efforts of Assistant Professor Akkhapun Wannakomol, Ph.D, my advisor, for his intellectual insights guidance; Professor Dr. Kittitep Fuenkajorn, Associate Professor Kriangkrai Trisarn, Dr. Chongpan Chonglakmani, Mr. Chatetha Chumkratoke for their intellectual insights guidance and encouragement to conduct this thesis.

The Exploration and Production Division Northern Petroleum Development Centre for giving an opportunity to use the data needed for this report.

All my friends and classmates, for their constant encouragement and moral support; and finally, my beloved parents for their constant and affectionate understanding, inspiration and unfading love.

Makara Laikanok

# CHAPTER I

## INTRODUCTION

### 1.1 Background and rationale

Production and exploration of petroleum at Fang Oil Field has been proceeding for over 50 years, but there is some spare amount of it (Settakul, 1985). According to the present day economic and political situation more studies of Fang oil field to increase its level of production are needed. Fang oil field is an intermontane basin where its average present production rate is about 1,000 barrel per day. These oils have been produced under the supervision of the Defence Energy Department (DED) by the Petroleum Development Act 1956. The majority of oil are produced from Mae-Soon oil field while the rest are from Nong-Yao, San-Sai, and Sam-Jang oil field which are located in Huai Ngu Sub basin (Petro Canada Resources, 1988). To study the distribution of oil-bearing formations, which is important in determining the amount of oil reserves and in oil and gas production wells planning, the applications of spatial information techniques can be applied.

Therefore, this study emphasis on the spatial distribution and the quality of petroleum reservoirs in the Mae-Soon oil field by applying Geographic Information Systems (GIS) and wireline logging techniques. The spatial information systems was used to collect, analyze and evaluate data of which could be displayed in a mapping format whereas the wireline logging techniques was used to study the quality of the potential reservoir in terms of its physical properties, e.g. porosity, permeability,

hydrocarbon saturation concentration. As a result, this spatial approach and analysis capable to increases the better concrete results in visual format of the distribution of the potential oil-bearing formations of Mae-Soon oil field.

## **1.2 Study area**

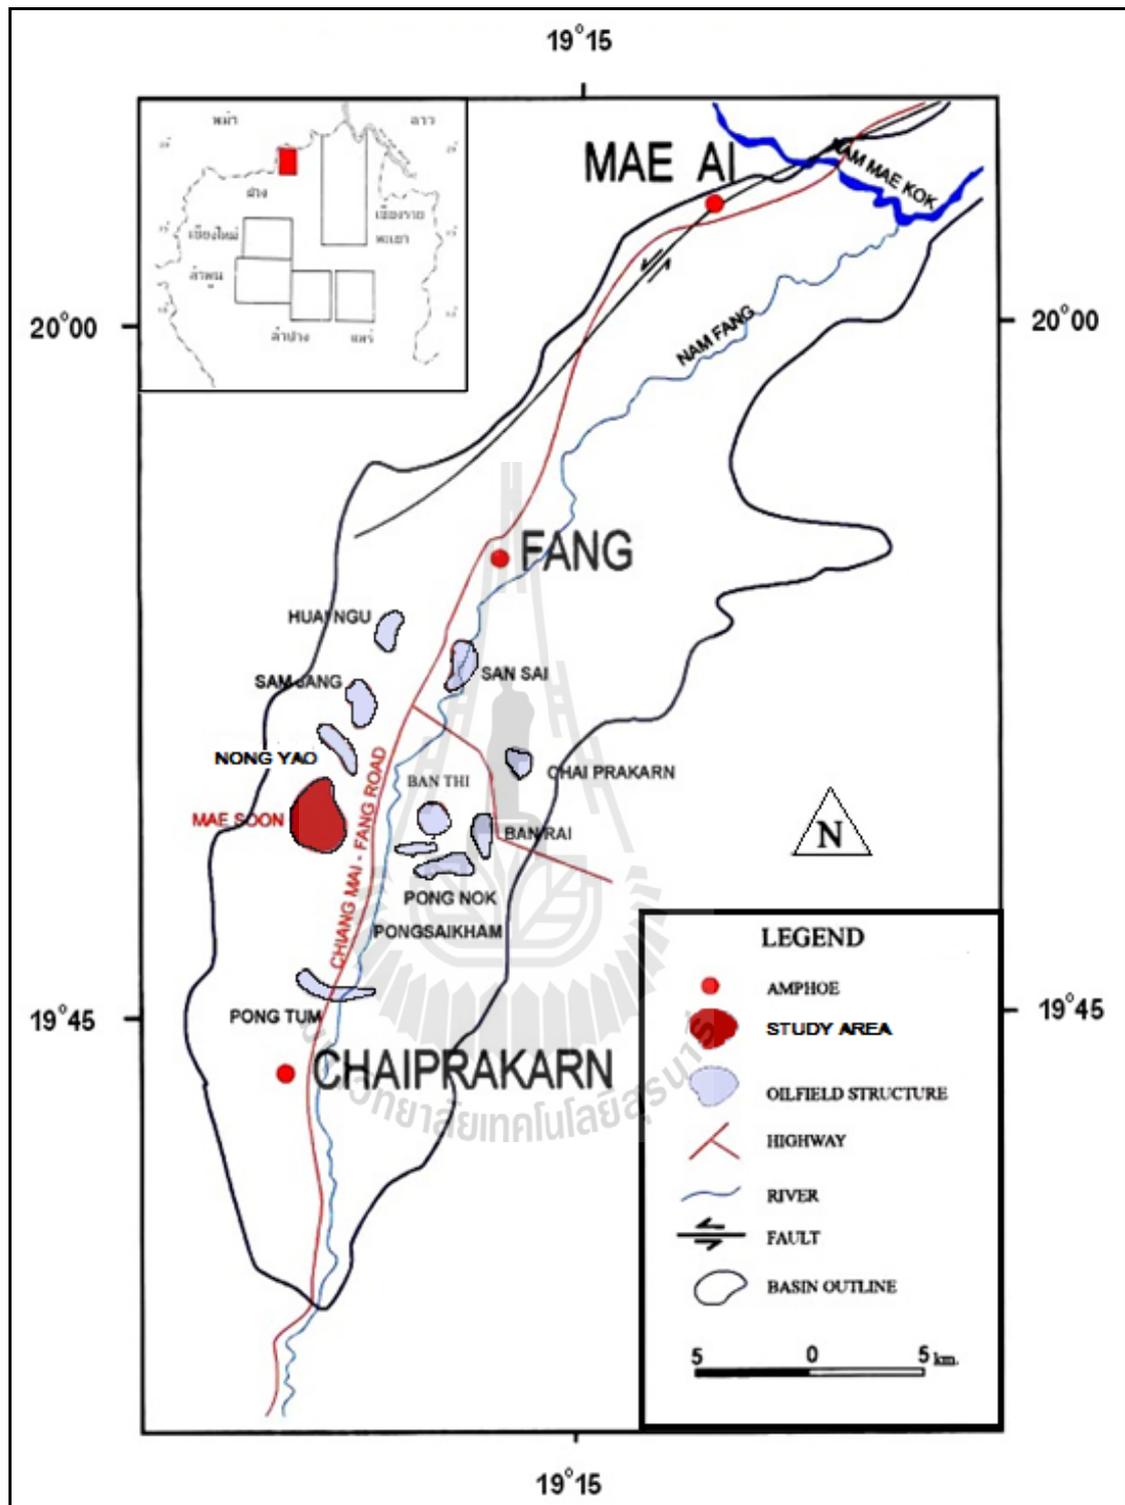

Mae-Soon oil field is located between latitude 19°49'16" and 19°53'24" North and between longitude 99°07'35" and 99°11'28" East (Figure 1.1). It covers an area of about 5 square kilometers including the area of Ban San Par Dang, Ban Huang Ao, Ban San Ton Muang and Ban Nong Yao, Mae Soon Sub district, Fang district, Chiang Mai province.

## **1.3 Objectives of the study**

The thesis aimed to analyze spatial distribution and quality of the potential petroleum reservoirs in the Mea-Soon oil field, Fang basin, by using Geographic Information Systems (GIS) and wireline logging data as the tool for mapping and demonstrating distribution and determine quality.

## **1.4 Scope and limitation of the study**

The study is focused mainly on the spatial distribution and determine the quality of petroleum reservoirs in the Mae-Soon oil field. This research uses the subsurface data including lithological logs, wireline logs, and 2D seismic profiles stratigraphic, reports of 33 boreholes drilled in Mae-Soon oil field which were provided by the Thai Defense Energy Department.

**Figure 1.1** Structure of oil field in Fang Basin (modified after Polachan and Sattayarak, 1989)

## 1.5 Research methodology

Research strategies and activities had been performed as followings:

1. Relevant literatures were searched, reviewed, summarized and documented.
2. Subsurface data including lithological logging, wireline logging data of 33 boreholes in the study area were collected, calculated, and interpreted in order to generate porosity, permeability, hydrocarbon saturation and isopach map.
3. ArcGIS, Surfer8, and Rockwork14 software were used in this study as tools for mapping and demonstrating distribution and determine quality of the potential petroleum reservoirs.

## 1.6 Thesis contents

**Chapter I** introduces the thesis by briefly describing the background and rationale of the study, the study objectives, methodology, scope and limitations of the study. **Chapter II** summarizes the results of the literature review. **Chapter III** describes the methodology of the study. **Chapter IV** shows the results and some discussions on the study. **Chapter V** concludes the study results and provides some recommendations for future study, respectively.

## **CHAPTER II**

### **LITERATURE REVIEW**

#### **2.1 Geology of the Fang Basin**

The geology of the Fang Basin and the adjacent areas were previously studied by numerous workers, namely, Dutescu et al. (1980), Bunopas and Vella (1983), Braun and Hahn (1976), Settakul (1985).

The Fang Basin is located on the western side of the Sukhothai Fold Belt, which comprises Paleozoic and Triassic strata and volcanic rocks that were accumulated on the eastern margin of the Shan-Thai Craton prior to the Indosinian orogeny. This fold belt is complex and trends north and northeast southwest. These rocks were uplifted and deformed by granitic intrusions during the collision of the Indochina and the Shan-Thai Craton (Bunopas and Vella, 1983). The base of sedimentary sequence in Fang Basin is marked by unconformity as a result of a great period of erosion that preceded the sedimentation of Miocene-Pliocene deposits. At the end of Pliocene the series of deposits was followed by sedimentation of fluvial environment.

The Fang Basin was filled with rocks of Tertiary and Quaternary age. These Cenozoic rocks and sediments consist of shale, sandstone, conglomerate, sand and gravel (Braun and Hahn, 1976) which is then modified and published by the Department of Mineral Resources (DMR) in 2007 (Figure 2.1 and Figure 2.2).

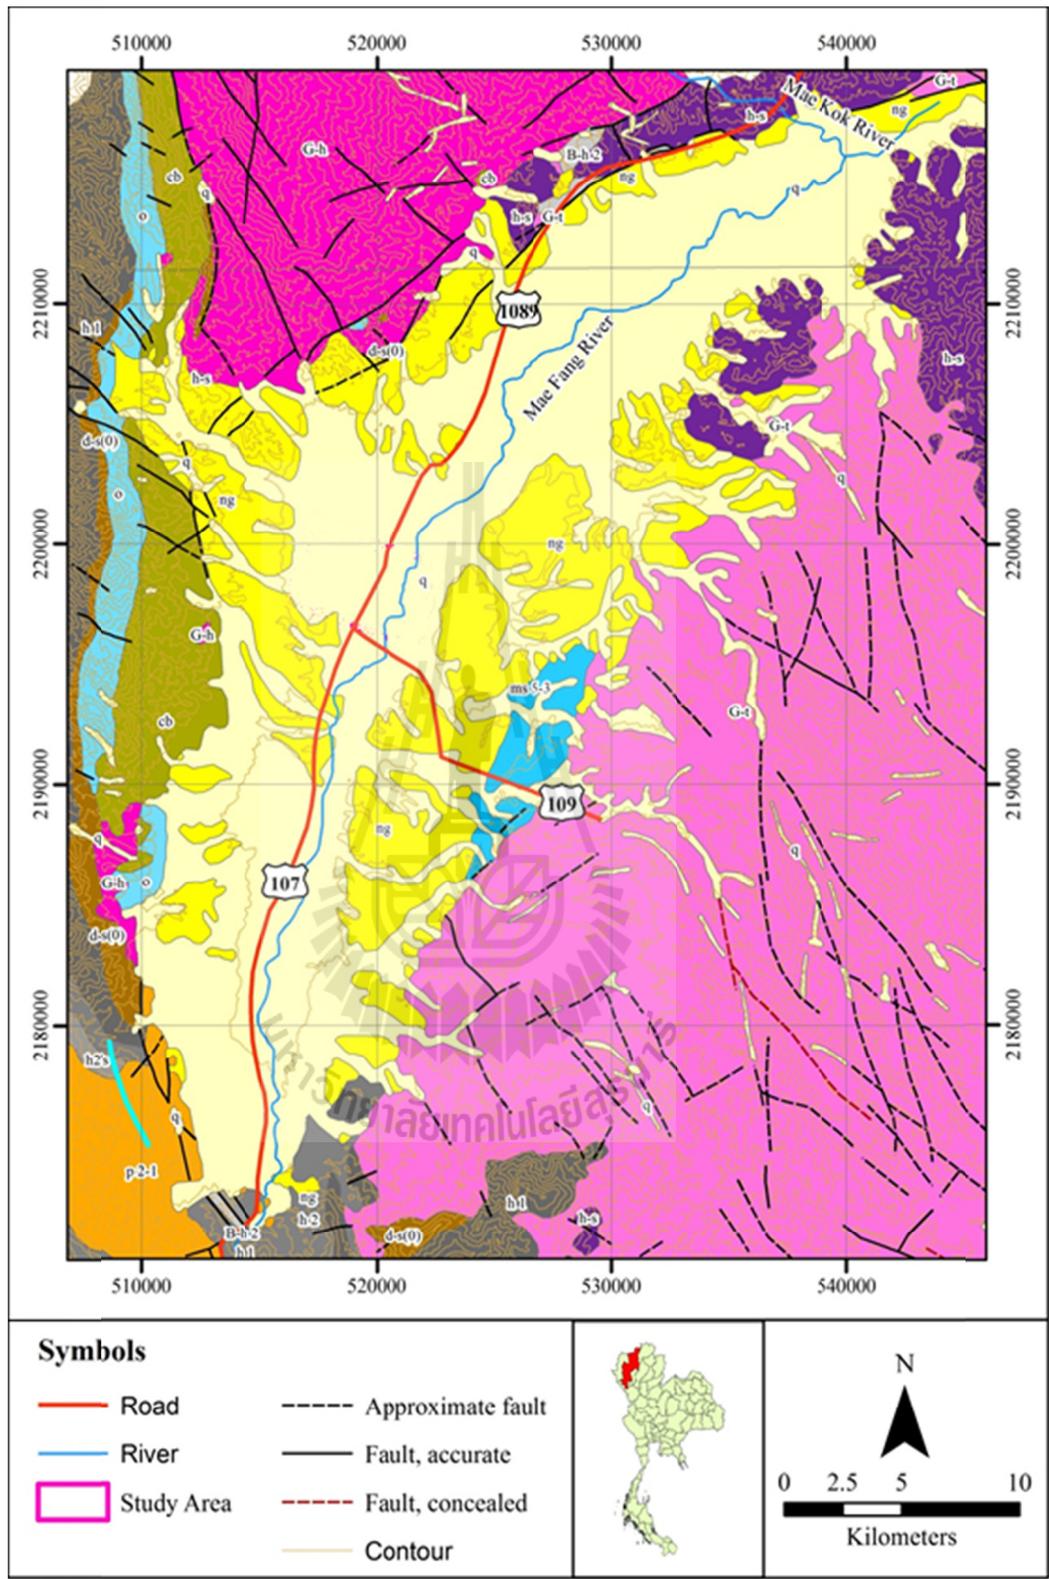

Figure 2.1 The geological map of Fang area and the study area is bounded by (modified after DMR, 2007).

**Figure 2.2** The geological symbols of Fang area (modified after DMR, 2007).

The character of lacustrine deposit of Miocene-Pliocene age is indicated by numerous coal seams and carbonaceous sediments. The dominant lithologic type of Miocene-Pliocene deposits is dark clays and sandy clays with lignite. The Fang Basin was subsided in the central part with about 3,000 meters thick of sediment accumulated. The wedging out of the beds and the prograding sedimentation are characteristics of fluvial-deltaic zone (Dutescu et al, 1980).

Settakul (1985) classified sediments and rocks in the Fang Basin into 2 units. These units are the Mae Fang Formation and the Mae Sod Formation. The depositional environment in the Tertiary time was fluvial-lacustrine and changed to fluvial and alluvial in Quaternary time. The Tertiary rocks of the Fang Basin are conglomerate, sandstone, claystone and shale. The Quaternary deposits are silt, clay, sand and gravel and they occur as stream channels, terrace deposits and alluvial fans. These sediments are covered by recent soil and lateritic sand. The pre-Tertiary basement rocks consist of sedimentary, metamorphic and igneous rocks. On the western side of the basin, the rocks are Cambrian-Permian age and include Carboniferous granite. On the eastern side of the basin, the rocks are Silurian-Devonian and Jurassic, along with Triassic granite.

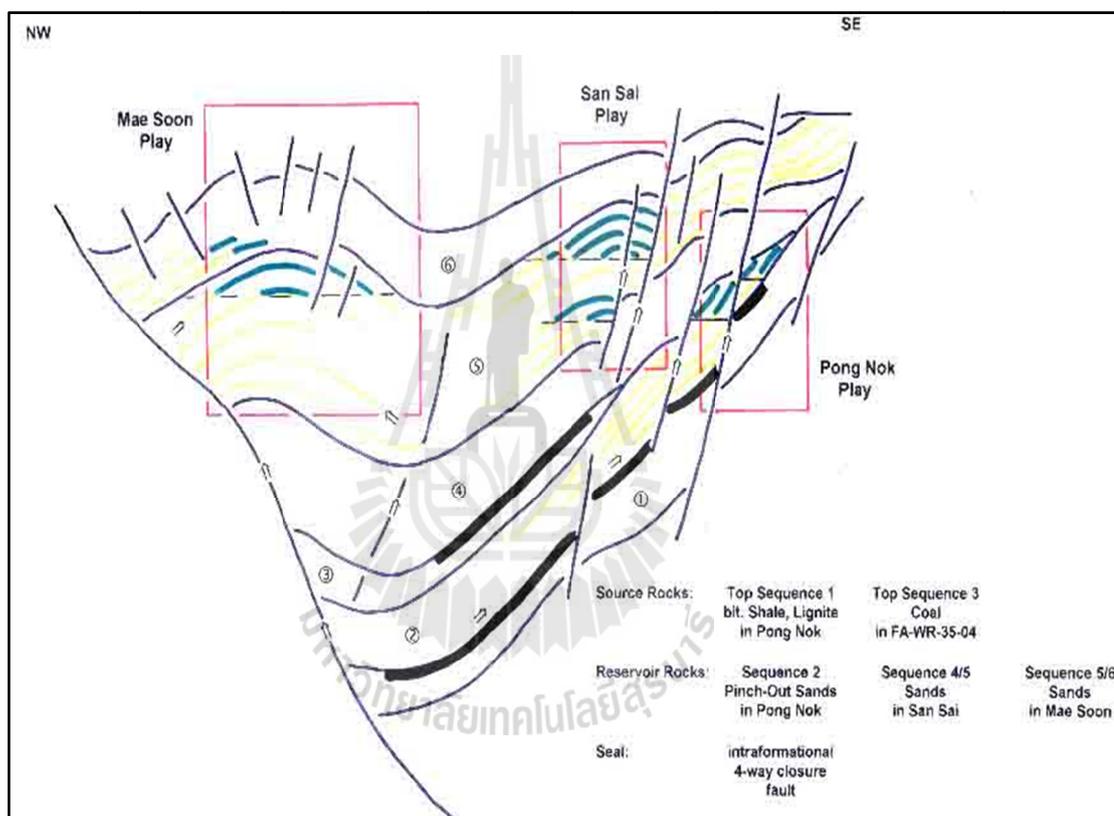

## **2.2 Petroleum geology of the Fang Basin**

Historically, the Fang Basin area is well known for oil seeps and the first petroleum production in the country was established here over five decades ago. The basin is divided by strike-slip faults into 3 sub-basins separated by horst of older rocks. The Miocene-Pliocene lacustrine sediments of the Mae Sod Formation are the main exploration target, with sediment in the main depocentre including organic-rich shales,

lignites and reservoir quality sandstone. The oils are waxy and were sourced from fresh water lacustrine shales which contained a high proportion of algal material (Petersen et al., 2006). Maximum Tertiary sediment thickness is 3,000 meters. The geothermal gradient is high at 7.5°C/100 meters and possible as high as 9.3°C/100 meters. (Petersen et al., 2006). The onset of oil generation is at 1,400 meters depth, which indicates that the main source-rock interval has been generating oil for about 6 Ma. The onset of wet gas generation is 1,900 meters. The deepest part of the basin is at 3,500 meters. Five small oil fields have been discovered to date and yield a total production rate of 800 bopd (with a historical maximum of 1,500 bopd). These fields produced from Miocene fluvial sandstones in a variety of traps including rollovers and possibly stratigraphic traps. The estimated original reserve of these fields was 50 MMbbl. According to the Department of Mineral Fuels, 2.7 MMbbl proven recoverable reserve remains. The first discovery was the Chai Pra Karn Field in 1953 which encountered a combined structural and/or stratigraphic trap at 230 meters. depth with production from coarse fluvial-lacustrine sandstones of the inferred Mae Sot Formation, sourced and sealed by lacustrine shales of similar age. The reservoir interval comprises thin poorly sorted sands in an interval of 30-100 meters. thick. Twenty wells were drilled on the field with production rates of 10-35 bopd per well. The field was abandoned in 1974, having produced 200,000 barrels of 16°API oil.

Mae-Soon oil field was discovered in 1961 and comprises a simple roll-over on the Mae-Soon Fault in the center of the basin (Figure 2.3). It has reserves of 3.5 MMbbl of 28.3°API oil with high wax content (15.6%). Thirty wells have been drilled, with one reaching basement at 1,005 meters. The reservoirs are stacked, fluvial-lacustrine sandstones of the Mae Sot Formation at 580-690 meters and 730-770

meters depth. The net pay of individual sandstone reservoirs is 2-5 meters and they are separated by inter-bedded shale and mudstones. Porosities are 22-26% and permeability are 552-2,026 md. Oil has been produced from 12-18 wells since 1970 and the field-production rate has averaged 91,000 bbls per year from the upper interval and 120,000 bbls per year from the lower interval.

**Figure 2.3** Diagram of petroleum system of Mae-Soon and San-Sai plays (Defence Energy Department, 2006).

The Pong Nok Field was discovered in 1979 and produced 30,000 barrels per year of 37°-38°API oil from four wells but is now abandoned. The San Sai discovery was made on the eastern margin of basin and flowed 300 bopd of 33°API oil from

possibly Pliocene sands at 1,280 meters from a combined structural and stratigraphic trap. The Nong Yau discovery produced 600 bopd from one well.

### **2.3 Other research use ARCGIS for study**

Harding (2008) presented ArcGIS used to analyze water access in Mae La, Thailand, home to 45,000 residents living as refugees in a temporary camp. Drinking water for the shelter is supplied at public tap stands while water for hygienic purposes such as bathing and laundry is available via covered rope-pump wells which reach shallow ground water; stream and river surface water; and hand-dug wells. In all 7,117 homes were identified using Google Earth and the corresponding proximity to the nearest tap stand and rope-pump well was calculated. ArcGIS was used together with an EPANET water-distribution model created by Rahimi (2008) to evaluate the predicted daily volume of drinking water available per home. Overall this research shows that the vast majority of residents in Mae La have sufficient access to water. Homes located further than 115 meters from a tap stand, located further than 180 meters from a rope-pump well, or having access to less than 50 liters of water per day were considered a cause for concern. Approximately one in four homes met these criteria. Only 5% of homes are located more than 115 meters from a tap stand. Approximately 14% of homes did not meet the rope-pump proximity criterion, and 15% of homes did not meet the available volume criterion. The tap-stand proximity results provide a much higher degree of confidence compared to the other results. Alternative sources for hygienic water besides rope-pump wells exist, suggesting the number of homes with sufficient access to hygienic water is likely underestimated. Flow rates, predicted by the EPANET model, are highly dependent on the elevation of

distribution system infrastructure points (e.g. storage tanks and tap stands), which are difficult to determine accurately. Thus, while the final results show one in four homes are a cause for concern, the reliability of the rope-pump well proximity assessment and volume per home assessment is insufficient, and the findings could be overly pessimistic.

Lagason (2008) reported Flood-map modeling that an integral part in determining flood-prone areas. This information will help planners and local authorities of future development in the areas affected, propose mitigation measures and also contingency plan in case of flooding. In this research, Geographic Information System (GIS) is coupled with HEC-RAS to produce a flood map of Kota Marudu. GIS provides a broad range of tools for determining area affected by floods and for forecasting areas that are likely to be flooded due to high water level in a river. HEC-RAS is capable of performing one-dimensional open channel steady-state hydraulics. In ArcView, Triangular Irregular Network (TIN) is developed for floodplain processing. Stream centerline, Bank, flow paths and cross sections are digitized to prepare the floodplain geometry for further analysis in HEC-RAS. The rainfall data is taken as 150 mm/hr from the IDF curve. Thus, the obtained flow rate using Rational method is 498.8 m<sup>2</sup>/s. A flood map is later produced for the Kota Marudu floodplain the depicts the flood depth and extent for 100 years ARI.

Ing, Cajthaml, and Hutchinson (2008) explained annual 90m x 90m resolution raster datasets of mean temperatures covering the Czech Republic were created for the 1998-2007 period in ArcGIS using linear regression. Linear regression was based on correlation between dependent climate variable – mean temperature and independent variable – altitude. Altitude information was taken from a digital elevation model

(DEM) acquired by the Space Shuttle Radar Topographic Mapping Mission (SRTM). Climate data were obtained from a small subset of meteorological stations (22 stations total) supervised by the Czech Hydrometeorological Institute. Annual variation in mean temperature was visualized in an animated map and published on the Internet. Mean temperature maps were published as a web map service. This web-based environment was created using ArcGIS Server software using a web server managed by the Department of Geography at Kansas State University.

Hasani (2013) presented several methods have been presented to flood administration and reduction and the results of flood risks until now. One of the employed methods is the Flood Plain Zoning (FPZ) method using hydraulic analysis that is based on a hydraulic model. Hydraulic models can draw the water surface profile in each arbitrary section. At first, the flood period is given; then the water surface level in different cross sections is calculated using the model, subsequently these points over the topographic plan of the zone are compared, to find the flood plain zone; and finally we can make required predictions to flood administration on the risk of flood. The current case study is an interval of Zaringol river in Golestan province in Northern Iran which is 24,210 meters long. Golestan province is the first region in Iran with the most detrimental floods and is always at risk because of its position, so presentation of accurate methods to determination of the accurate plain zone of flood is necessary to prevent the probable risks. To this end, the hydraulic model of HEC-RAS to hydraulics calculations and the ArcView software are employed to extract the cross section using topographic plans of river and FPZ in Geographical Information System (GIS) with flood periods: 2, 5, 10, 50 & 100 years and the scale of plans is 1:10000. The zones that were at risk were determined and finally several methods were

recommended to prevent the zone reduction and the detriments of flood. This inquiry completely showed that incorporation of the hydraulic model of HEC-RAS and GIS is a useful implement to analyze FPZs.

# **CHAPTER III**

## **METHODOLOGY**

### **3.1 Wireline log data interpretation**

In this study gamma ray (GR), spontaneous potential (SP) and resistivity logs data of Mae-Soon oil field were gathered from 33 boreholes and were interpreted. These wireline logs data were provided by the Exploration and Production Division of the Northern Petroleum Development Center. These log data were used to identify rock type and rock properties within boreholes, e.g. porosity and permeability. Borehole names and location used in this study are listed in Table 3.1 and Figure 3.1.

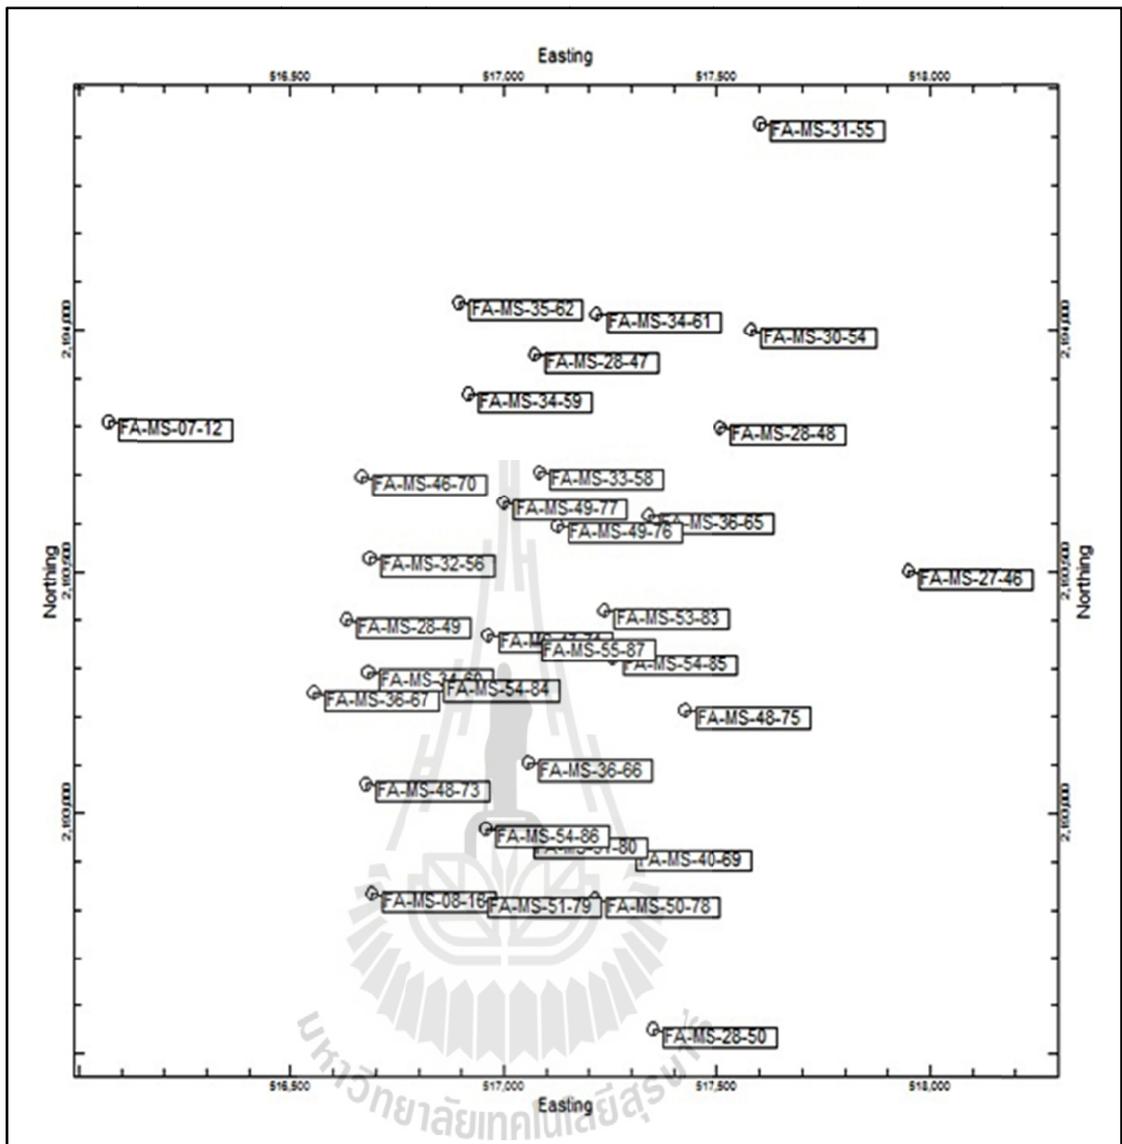

#### **3.1.1 Gamma ray (GR) log**

The GR log records the radioactivity of the formation along the borehole. The GR reading tends to increase in proportion to the amount of clay present in sediment, which tends to increase with decreasing particle size. Therefore, the GR log can be used as a grain size profile. Sand line (lowest GR) and shale base line (highest GR) values can be calibrated to particle size. Pure coals have low GR response while shaly coals have a GR value which depends on the shale content. High GR values often correspond to source rock interval rich in organic matters, but such intervals do not always have a high GR value. The contrast between pure coals and organic shales is remarkable, and often seen in cyclic deltaic sequences, where a low GR coal is overlain by a high GR, organic rich shale. GR peaks in shale sequences representing condensed sections or maximum flooding surface (MFS). Quartzite shows

no radioactivity and sandstone usually shows low GR values (Jankaew, 2002). In this study GR log data had been used to separate shale bed from sandstone bed since it has a great amount of gamma ray compared with sandstone.

**Figure 3.1** Location map of the 33 boreholes which were used in this study.

### 3.1.2 Spontaneous potential (SP) log

SP log measures the natural electric potential of formation. It is measured in millivolts on relative scale only because the absolute value of the potential depends not only on the properties of the rock and interstitial fluid, but also on the properties of the drilling mud. The SP log is used to detect bed boundaries, identify permeable zones, calculate formation water resistivity, and determine the volume of shale (shaliness) in permeable beds. The SP response is relatively constant in shaly sections and it is used to define a “shale line”. Zones of permeable bed containing interstitial fluid with a salinity contrast to drilling mud are indicated by deflections from shale line. The SP log will be a good lithological indicator if it is calibrated against cores and cuttings (Chinabutr, 1987). Lithological interpretation of SP logs shape is similar to those of GR logs, i.e. changes in SP log response are in the same direction as GR logs. Thus, SP and GR logs are substituted for one another in the absence of the other in interpreting lithology.

### 3.1.3 Resistivity log

Resistivity logs respond to two features involving change in texture and change in composition. Compositional changes include changes in organic matter content and amount of silt. Facies and facies change can be followed on the resistivity logs. A resistivity log can register changes in quartzose (sand) - shale mixtures where an increase in resistivity corresponds to an increase in the silt (quartz) content.

Textural variation such as fine lamination of organic rich shale causes distinctive, low resistivity. Resistivity of rock is closely related to texture, e.g. when porosity decreases resistivity increases. High resistivity values may indicate a porous, hydrocarbon-bearing formation. Hydrocarbons have very high resistivity contrast with

aqueous fluids, which have high conductivities. There are no characteristic resistivity limits for shale or limestone or sandstone. The values depend on many variations, e.g. compaction, composition and fluid content. High resistivity will also be associated with tight limestone and dolomite (Jankaew, 2002).

To identify rock type in this study gamma ray, spontaneous potential, and resistivity logs data were interpreted according to sandstone type classification guideline of DED (Table 3.2) together with the mud logging data of 33 boreholes which were drilled in Mae-Soon oil field and then sandstones of each well could be classified into 19 layers (Table 3.3), respectively.

**Table 3.2** Sandstone type classification guideline based on resistivity data and mud logging data (modified after DED).

Sandstone type	Depth (feet)	Long resistivity (ohm-meter)	Short resistivity (ohm-meter)	Ratio (%)
very fine Lithic Greywacke	1,400-2,600	40	12	0.30
fine Lithic Greywacke		94	31	0.33
Intermediate Lithic Greywacke		110	40	0.36
Coarse Lithic Greywacke		140	54	0.39
very fine Quartz Wacke	2,600-3,500	20	8.3	0.42
fine Quartz Wacke		71	32	0.45
Intermediate Quartz Wacke		124	60	0.48

**Table 3.3** Total thickness of 19 sand layers of 33 boreholes drilled in Mae-Soon oil field.

<b>Sandstone layer</b>	<b>Range (feet)</b>	<b>Total Thickness (feet)</b>	<b>Mean (feet)</b>	<b>Max (feet)</b>	<b>Min (feet)</b>
Layer 1	1295-1730	435	20	60	5
Layer 2	1450-1844	395	18	64	5
Layer 3	1540-1992	452	14	28	5
Layer 4	1574-2028	454	16	70	5
Layer 5	1642-2085	443	21	56	5
Layer 6	1777-2140	363	16	48	4
Layer 7	1868-2260	392	20	68	6
Layer 8	1972-2340	368	17	41	4
Layer 9	2014-2430	458	19	72	4
Layer 10	2124-2530	406	20	58	5
Layer 11	2150-2636	486	16	52	5
Layer 12	2248-2688	440	17	58	5
Layer 13	2322-2720	398	15	38	5
Layer 14	2410-2800	390	17	44	7
Layer 15	2456-2879	423	14	36	4
Layer 16	2534-2970	436	16	40	4
Layer 17	2628-3110	482	15	34	5
Layer 18	2704-3312	608	15	32	5
Layer 19	2815-3434	619	17	32	5

## 3.2 Porosity and permeability

### 3.2.1 Porosity

Porosity is the ratio between the volume of all spaces to the total volume of the rock mass and porosity indicates the volume in the storage of liquids or gases in the rock (Selley, 1976). Porosity depends on sorting and grain shape (Mayer-Gurr, 1976). Porosity has two types which are 1) absolute (total porosity) as a percentage of the gap in the rocks and 2) effective porosity as a percent of spaces are connected (Pettijohn, Potter, and Siever, 1973 and Pettijohn, 1975). Dickker (1985) determined by the quality of the porosity of sandstone in term of its capacity retention based on porosity percent as depicted in Table 3.4.

**Table 3.4** The quality of sandstone based on permeability (after Dickker, 1985).

Porosity (percent)	Capacity retention
<10	poor
10-15	fair
15-25	good (mostly the oil bearing formations)
>25	very good (but a little)

### 3.2.2 Permeability

Permeability is the ability to allow the flow of liquid or gas through a gap in the rocks (Selley, 1976). Properties of the rock affects the permeability are viscosity, pressure gradient, capillary force, throats, tortuosity of space, geometry of pores, the effective porosity of the stone, grain size, cementation, orientation, packing of framework grains, sorting and bedding. Permeability changes in the vertically

upward direction and down is measured in Darcy. Pettijohn, Potter, and Siever (1973) indicates that permeability of the sandstone and siltstone (with small effective porosity) would be lower when grain size decreases. Surface area increases should result in obstruction of the flow of the fluid. Development of the interface surface area and porosity reduction sometimes cause the permeability to deteriorate. Muskat (1949) found that the permeability of the sandstone in the range of 5-5,000 milliDarcy. Dickker (1985) classified sandstone quality in term of its storage capacity based on permeability as depicted in Table 3.5.

**Table 3.5** The quality of sandstone based on porosity (after Dickker, 1985).

Permeability (milliDarcy)	Storage capacity
10	poor
100	fair to good
1000 (1 Darcy)	very good

### 3.3 Wireline log data calculation

Gamma ray (GR), resistivity, and spontaneous potential (SP) logs data were used to discriminate the subsurface lithology of 33 boreholes of Mae-Soon oil field based on the following steps.

#### Step 1 Sand and shale layers identification

The SP log data were used to separate hydrocarbon zone which are sandstone layers (SP-) and shale break (SP+) from each other. Then the result from SP log interpretation were rechecked by using gamma ray log data to clearly identify shale layers.

## Step 2 Potential hydrocarbon zones identification

### Porosity determination

Resistivity log data were used to determine porosity of sand layers of each boreholes. In this step, Formation factor (F) which is the ratio between the clean formation resistivity of rock saturated with water 100% ( $R_o$ ) and the electrical resistance of the water in all spaces of the rock layers ( $R_w$ ) were calculated by the following equation (Erickson and Stephanie, 1998).

$$F = \frac{R_o}{R_w} \quad (3.1)$$

From equation, it indicates that the formation factor (F) is directly proportional to the formation resistivity ( $R_o$ ). However, the formation factor (F) is inversely proportional to the porosity ( $\phi$ ) according to the Archie's equation as presented in equation 3.2.

$$F = \frac{0.62}{\phi^{2.15}} \text{ or } F = \frac{0.81}{\phi^{2.0}} \quad (3.2)$$

Therefore, the porosity of each interesting layer can be calculated from this relationship.

### Hydrocarbon saturation ( $S_{hc}$ ) determination

Hydrocarbon saturation ( $S_{hc}$ ) could be determined by known clean formation water saturation ( $S_w$ ) (Jordan and Rachel, 2011). Therefore, in this study the water saturation of each interesting zone was calculated by Archie's equation (equation 3.3)

$$S_w = \sqrt[n]{\frac{FR_w}{R_t}} = \sqrt[n]{\frac{R_o}{R_t}} \quad (3.3)$$

Where  $n$  = saturation exponent (generally 2.0)

$R_t$  = observed total resistivity

Thus, the hydrocarbon saturation ( $S_{hc}$ ) can be obtained from equation 3.4.

$$S_{hc} = 1 - S_w \quad (3.4)$$

### **Permeability determination**

Permeability values used in this study were obtained and supported by the Exploration and Production Division of the Northern Petroleum Development Center which were measured from core samples directly in laboratory.

Then porosity, permeability and hydrocarbon saturation data were used to classify the quality of the studied sandstone layers based on Muskat (1949) and Dickker (1985) theory.

### **Step 3 Lithostratigraphic correlation from wireline log data**

Lithostratigraphy obtained from wireline logs interpretation in the first and second step of each well was then correlated to each other and made up the lithostratigraphic correlation in the north-south and west-east direction.

### **Step 4 Database make up**

All acquired and obtained data from literature reviews, wireline log data interpretation and calculation, e.g. porosity, permeability, hydrocarbon saturation, sand layer thickness, were saved as in Microsoft Excel format and prepared for exporting to ArcGIS, Surfer8, and Rockwork14 program to generated maps.

The algorithm used by ArcGIS to calculate area is called the shoelace formula or Gauss's area formula. Thesis uses a normalized form of this formula to preserve numeric precision.

The algorithm calculates the area for each ring (part) in a polygon. If the ring is clockwise (outer ring) the area is positive, and if the ring is counterclockwise (inner ring) the value is negative.

A partial sum of a trapezoid's area is used where:

partialSums[0]	- Array of double
cPoints	- Number of points in the ring
points	- Array of point structure, the structure as X and Y as attributes
yOrigin	- Double equal to the Y value of the last point (cpoints-1)

The first trapezoid's area is:

$$\text{partialSums}[0] = (\text{points}[1].x - \text{points}[\text{cPoints}-1].x) * (\text{points}[0].y - y\text{Origin})$$

For each point starting at index 1:

for j = 1 to j < cPoints-1

$$\text{partialSums}[j] = (\text{points}[j+1].x - \text{points}[j-1].x) * (\text{points}[j].y - y\text{Origin})$$

If the ring contains nonlinear segments, such as Circular Arc, Elliptic Arc, and Bezier Curve, a correction of the area is applied for each trapezoid.

The final area of the ring is :           SUM(PartialSums)/2

The final area of the polygon is :       SUM(Area of each ring)

Here is an example with the following points (one square ring) zz:

$$X0 = 0; \quad Y0 = 0$$

$$X1 = 0; \quad Y1 = 10$$

$$X2 = 10; \quad Y2 = 10$$

$$X3 = 10; \quad Y3 = 0$$

$$X4 = 0; \quad Y4 = 0$$

$$\text{partialSums}(0) = (X0 - X4) * (Y0 - Y4) = (0 - 0) * (0 - 0) = 0$$

$$\text{partialSums}(1) = (X2 - X0) * (Y1 - Y4) = (10 - 0) * (10 - 0) = 100$$

$$\text{partialSums}(2) = (X3 - X1) * (Y2 - Y4) = (10 - 0) * (10 - 0) = 100$$

$$\text{partialSums}(3) = (X4 - X2) * (Y3 - Y4) = (0 - 10) * (0 - 0) = 0$$

There is no correction to apply in this case because only lines are used:

$$\text{sum}(\text{partialSums})/2 = 200/2 = 100$$

## **CHAPTER IV**

### **RESULTS**

#### **4.1 Wireline log data interpretation results**

The interpretation of the data in order to see the relationship of the sandstone layer. Interpretation will use the wireline logging and mud logging in view of the relationship of sandstone that has similar properties. It is used to divide the properties of the sandstone layers of the DED (Table 3.2) is determined. The potential of the sandstone layers is used to divide the property. Dekker (Table 3.4 and 3.5) is determined.

##### **4.1.1 Gamma ray, Spontaneous potential and Resistivity log interpretation**

Based on sandstone type classification guideline of DED (Table 3.2) and the mud logging data of 33 boreholes which were drilled in Mae-Soon oil field (Table 3.3) gamma ray, spontaneous potential data (Appendix A) and resistivity logs data (Appendix B) were interpreted and results from each wireline log interpretation was presented in Appendix A and Appendix B respectively.

##### **4.1.2 Sandstone layer thickness maps**

Method of create map:

1. From define the scope study area that needs to be studied.
2. The data in the study that there is sufficient data and collect the necessary data to create maps for most.
3. The data acquisition, processing and analysis in the form of files.

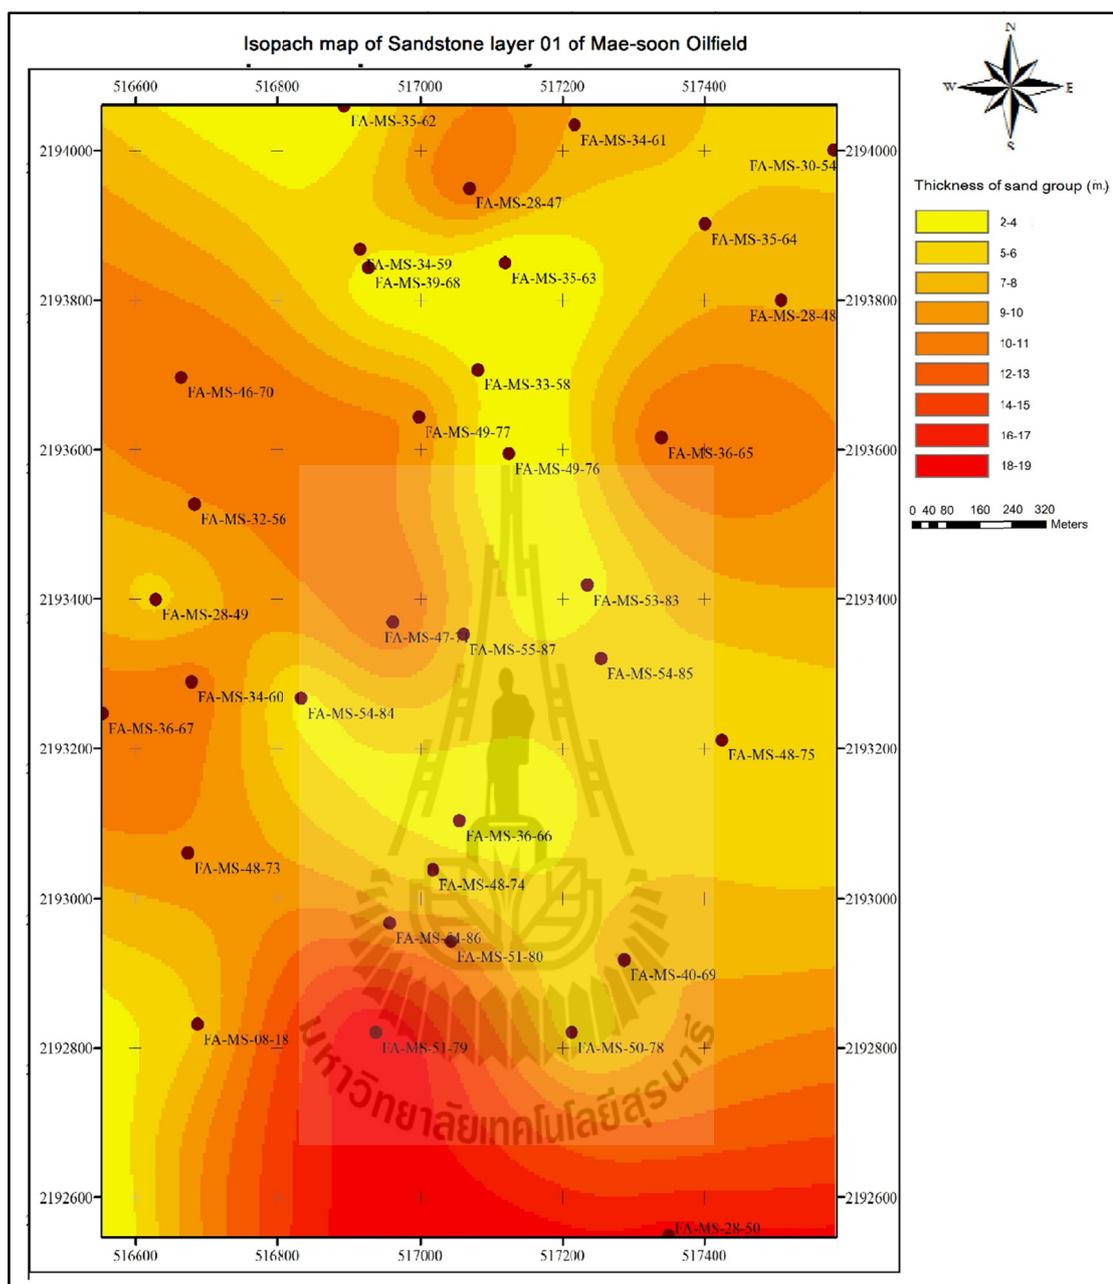

4. Data files into the program to create the map.

Results from gamma, spontaneous potential, and resistivity log interpretation in the previous step together with mud log data of selected 33 boreholes were then used to generate isopach map of 19 sandstone layers which are potential oil reservoirs of Mae-Soon oil field. Isopach map of identified 19 potential oil sandstone reservoirs are shown in Figures 4.1 to Figure 4.19, respectively.

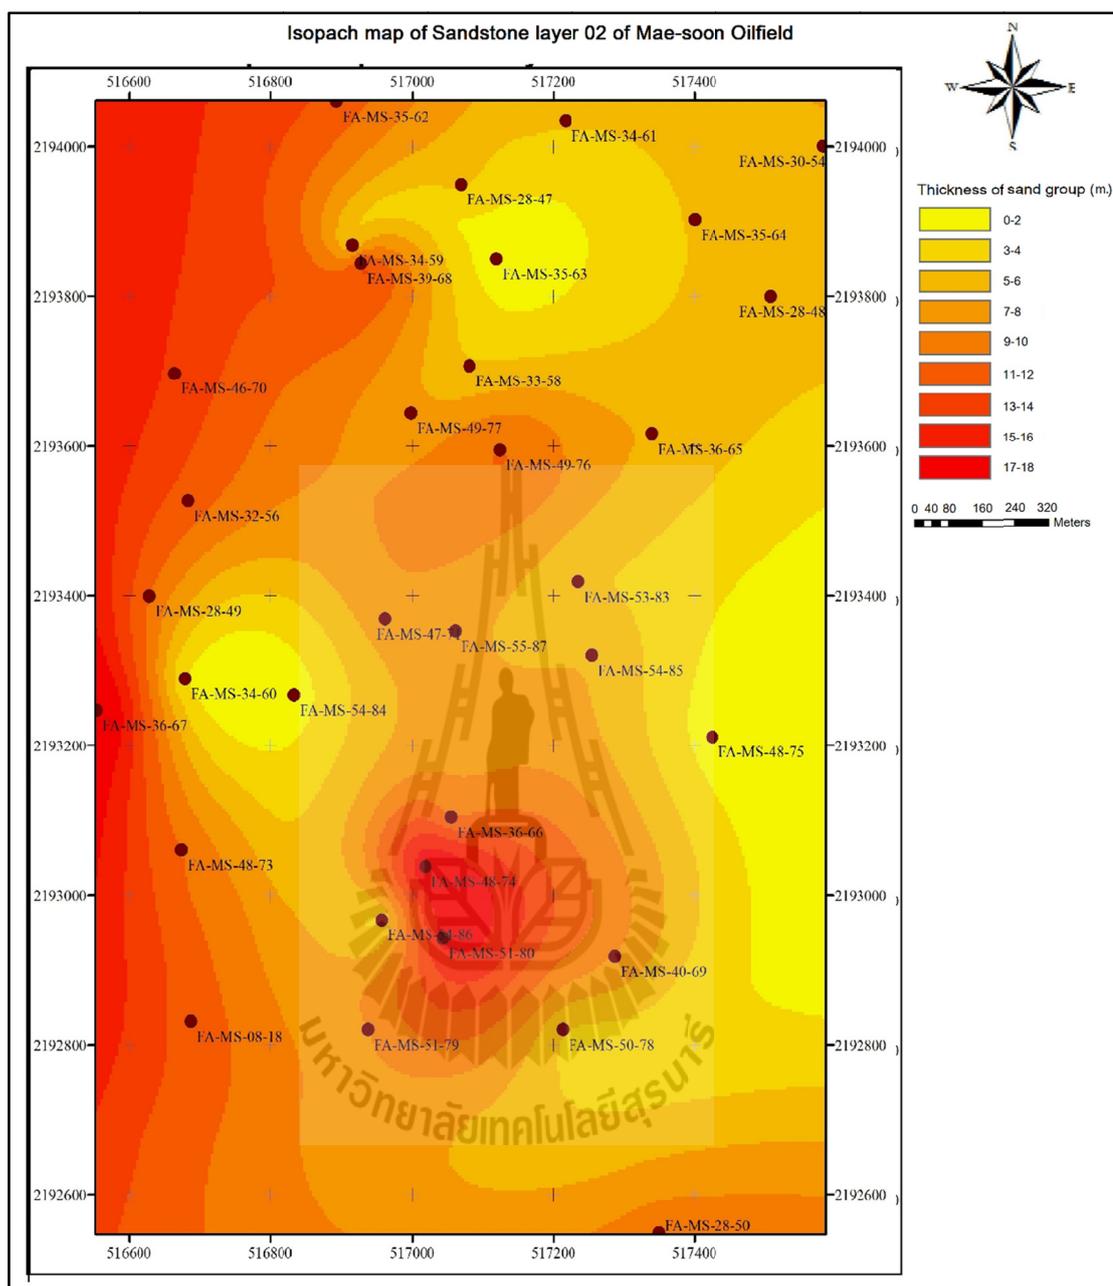

Figure 4.1 revealed the distribution of thickness of sandstone layer 01 in the study area. This layer is found at depth between 1,295 and 1,730 feet and the thickest (60 feet) is found at well no. FA-MS-51-79 whereas the thinnest layer (5 feet) is found at well no. FA-MS-49-76. This sandstone layer is very fine sand Lithic Greywacke with an average grain size of 0.07 millimeters. It contains 3% cementing material and 18% Matrix.

Figure 4.2 revealed the distribution of thickness of sandstone layer 02 in the study area. This layer is found at depth between 1,450 and 1,844 feet and the thickest (38 feet) is found at well no. FA-MS-36-68 whereas the thinnest layer (5 feet) is found at well no. FA-MS-35-63. This sandstone layer is very fine sand Lithic Greywacke with an average grain size of 0.09 millimeter. It contains 5% cementing material and 20% Matrix.

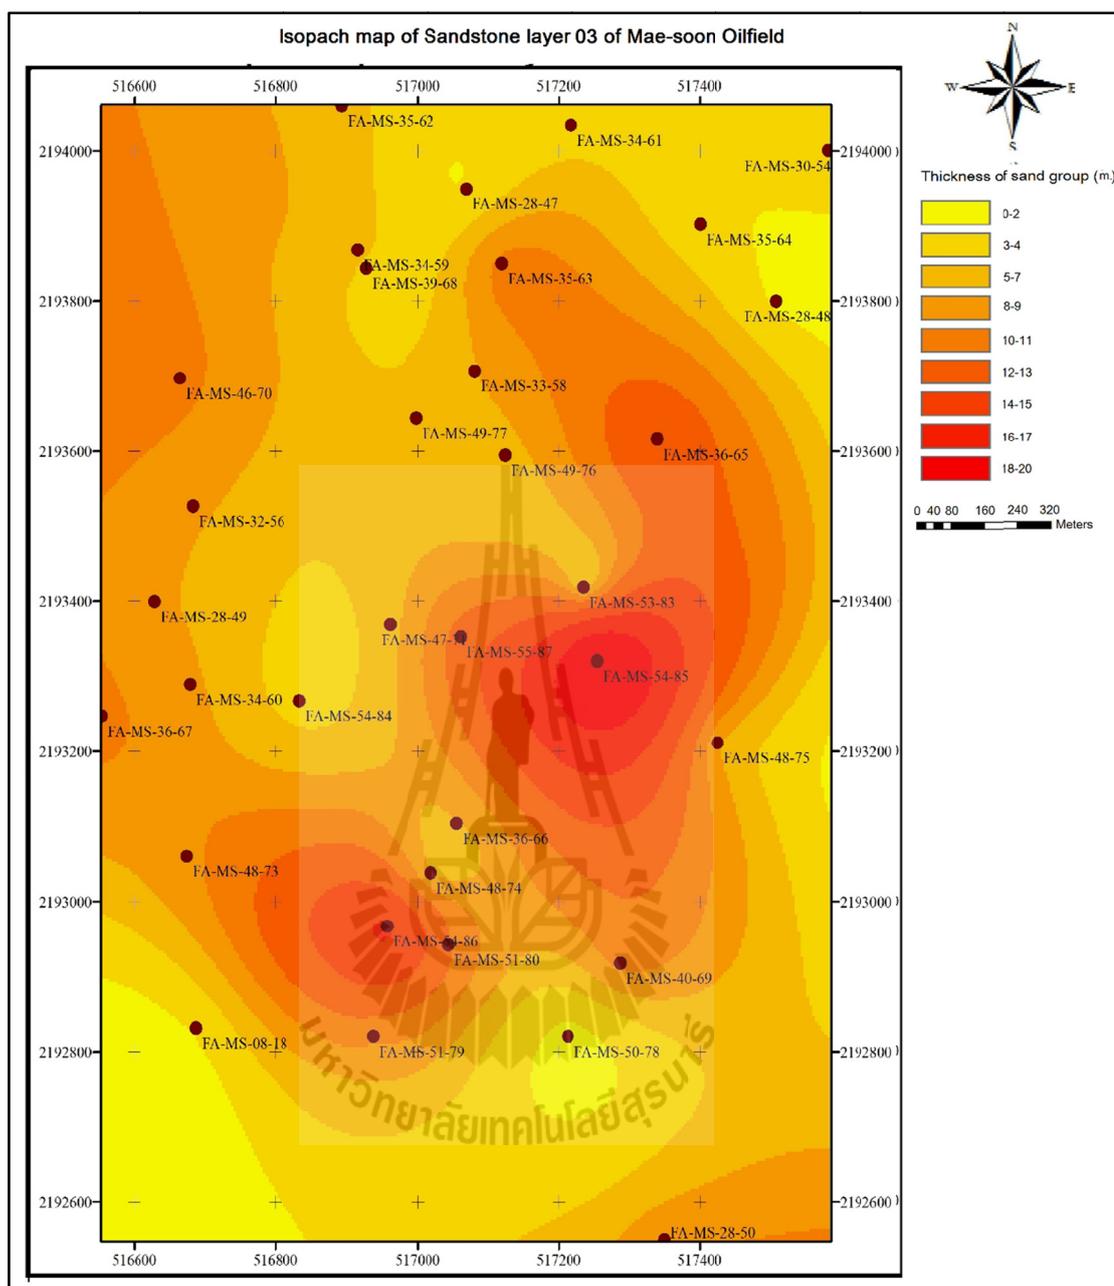

Figure 4.3 revealed the distribution of thickness of sandstone layer 03 in the study area. This layer is found at depth between 1,540 and 1,992 feet and the thickest (64 feet) is found at well no. FA-MS-54-85 whereas the thinnest layer (7 feet) is found at well no. FA-MS-28-48. This sandstone layer is fine sand Lithic Greywacke with an average grain size of 0.15 millimeter. It contains 3% cementing material and 18% Matrix.

**Figure 4.1** Isopach map of sandstone layer 01 of Mae-Soon oil field.

**Figure 4.2** Isopach map of sandstone layer 02 of Mae-Soon oil field.

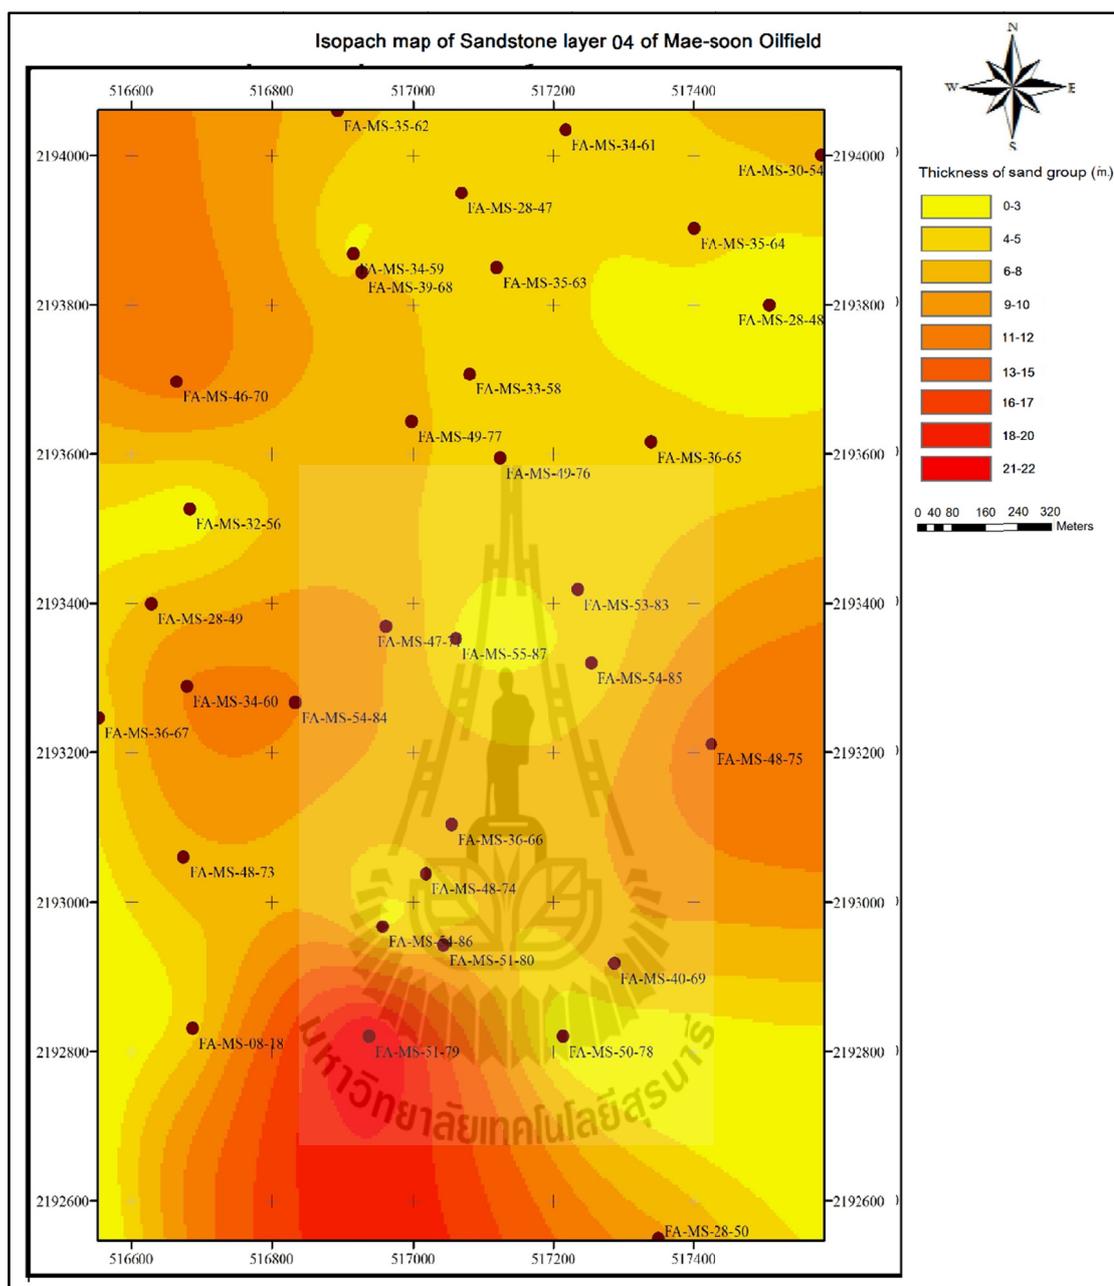

**Figure 4.3** Isopach map of sandstone layer 03 of Mae-Soon oil field.

Figure 4.4 revealed the distribution of thickness of sandstone layer 04 in the study area. This layer is found at depth between 1,574 and 2,028 feet and the thickest (70 feet) is found at well no. FA-MS-51-79 whereas the thinnest layer (5 feet) is found at well no. FA-MS-28-48. This sandstone layer is medium sand Lithic Greywacke with an average grain size of 0.2 millimeter. It contains 2% cementing material and 23% Matrix.

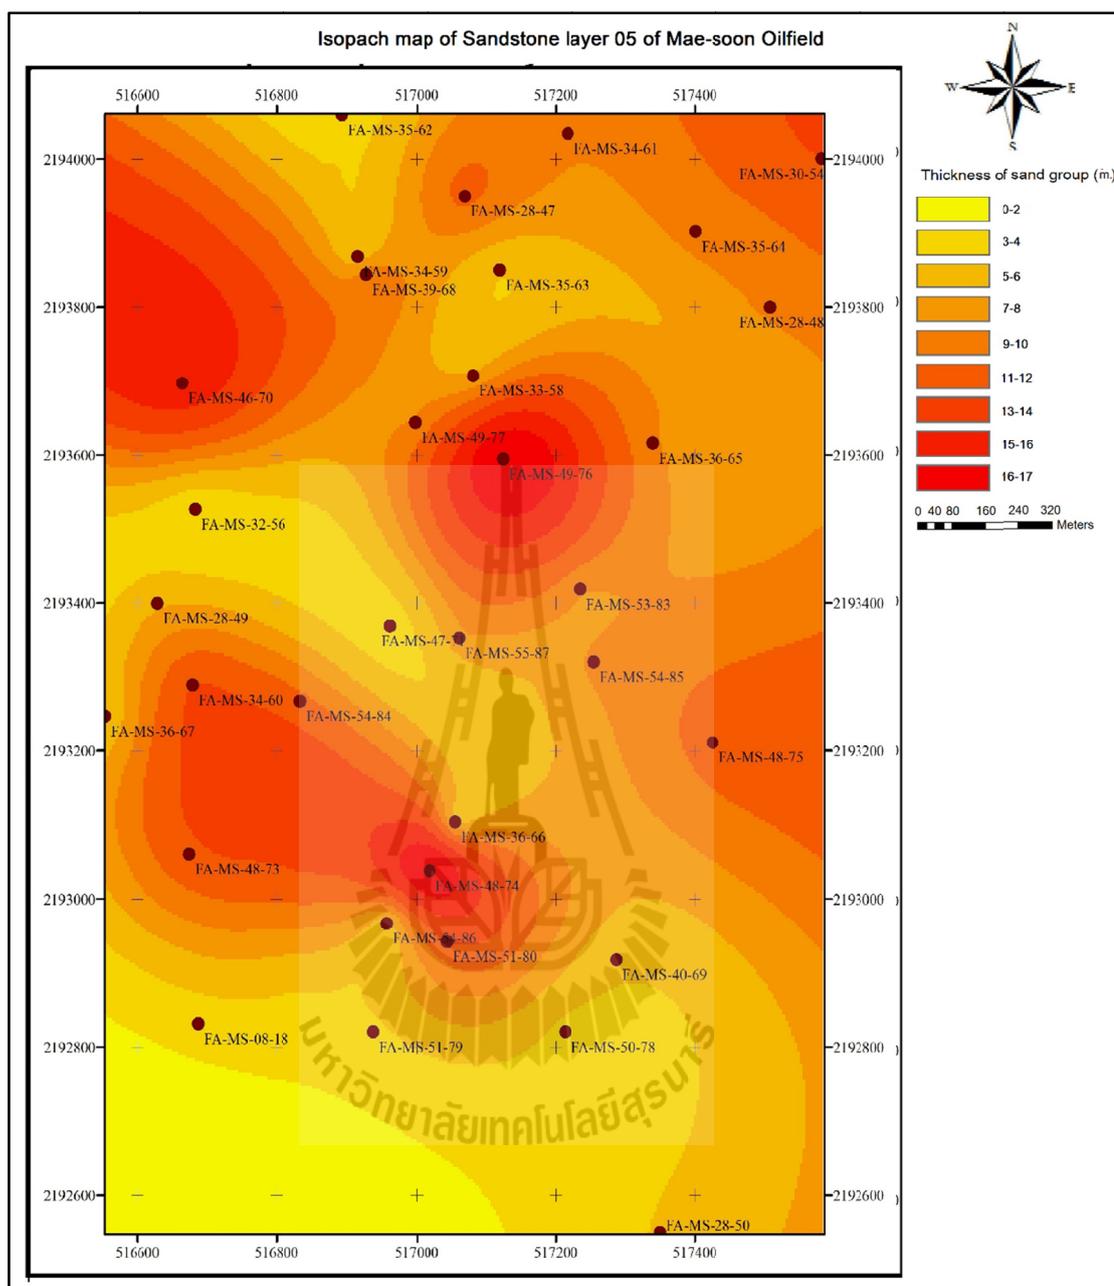

Figure 4.5 revealed the distribution of thickness of sandstone layer 05 in the study area. This layer is found at depth between 1,642 and 2,085 feet and the thickest (56 feet) is found at well no. FA-MS-49-76 and FA-MS-48-74 whereas the thinnest layer (5 feet) is found at well no. FA-MS-32-56. This sandstone layer is medium sand Lithic Greywacke with an average grain size of 0.2 millimeter. It contains 2% cementing material and 21% Matrix.

Figure 4.6 revealed the distribution of thickness of sandstone layer 06 in the study area. This layer is found at depth between 1,777 and 2,140 feet and the thickest (48 feet) is found at well no. FA-MS-48-73 whereas the thinnest layer (4 feet) is found at well no. FA-MS-48-75. This sandstone layer is medium sand Lithic Greywacke with an average grain size of 0.3 millimeter. It contains 3% cementing material and 25% Matrix.

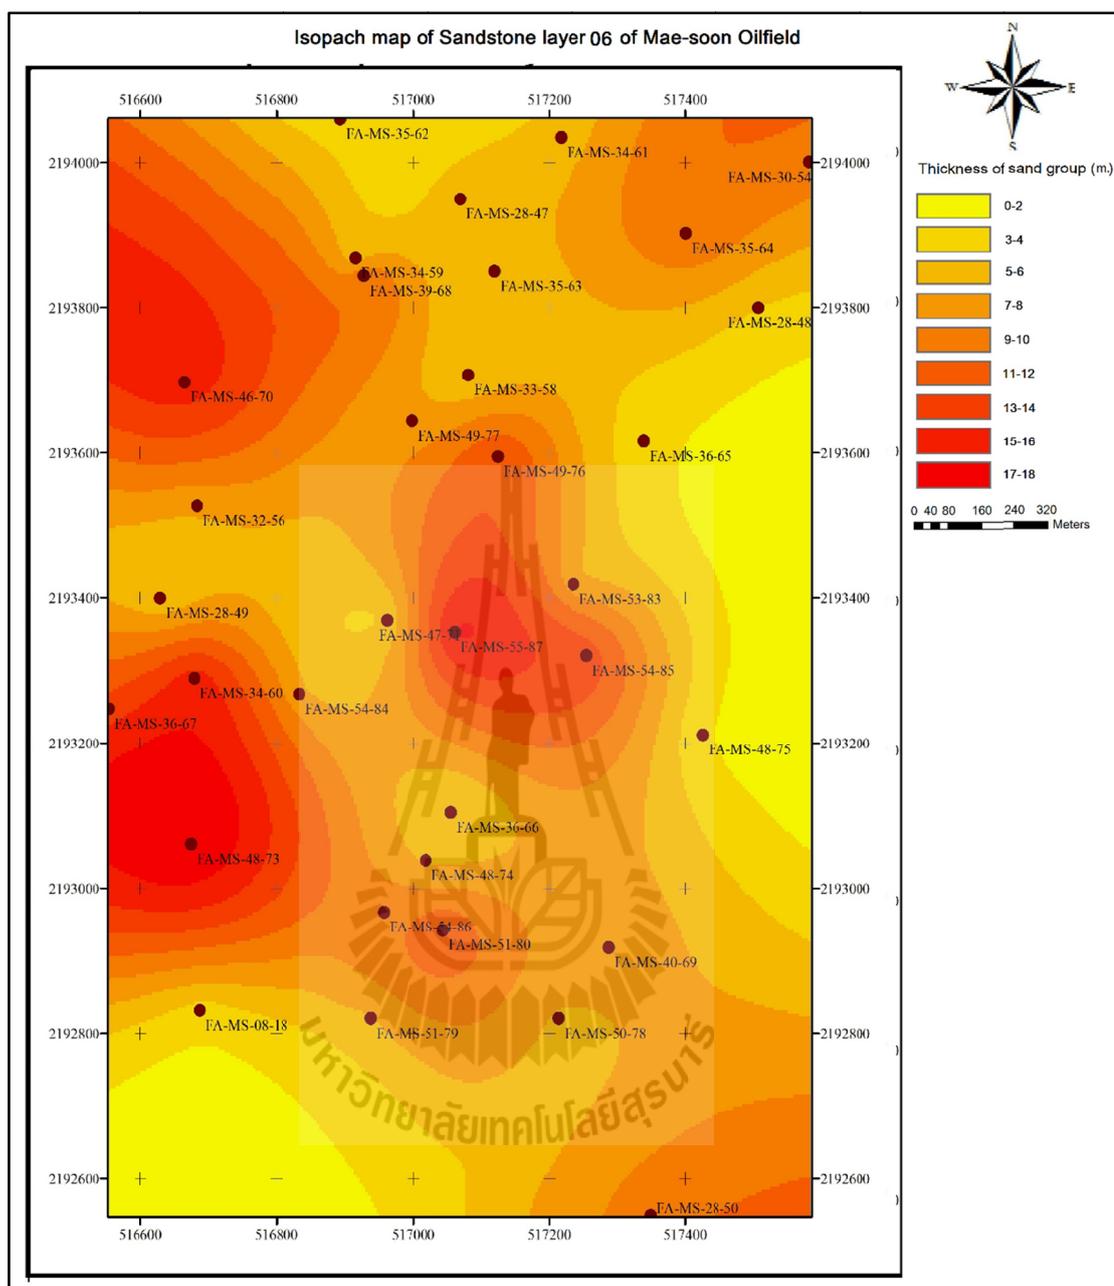

Figure 4.7 revealed the distribution of thickness of sandstone layer 07 in the study area. This layer is found at depth between 1,868 and 2,260 feet and the thickest (58 feet) is found at well no. FA-MS-46-70 whereas the thinnest layer (6 feet) is found at well no. FA-MS-33-58. This sandstone layer is fine sand Lithic Greywacke with an average grain size of 0.17 millimeter. It contains 2% cementing material and 20% Matrix.

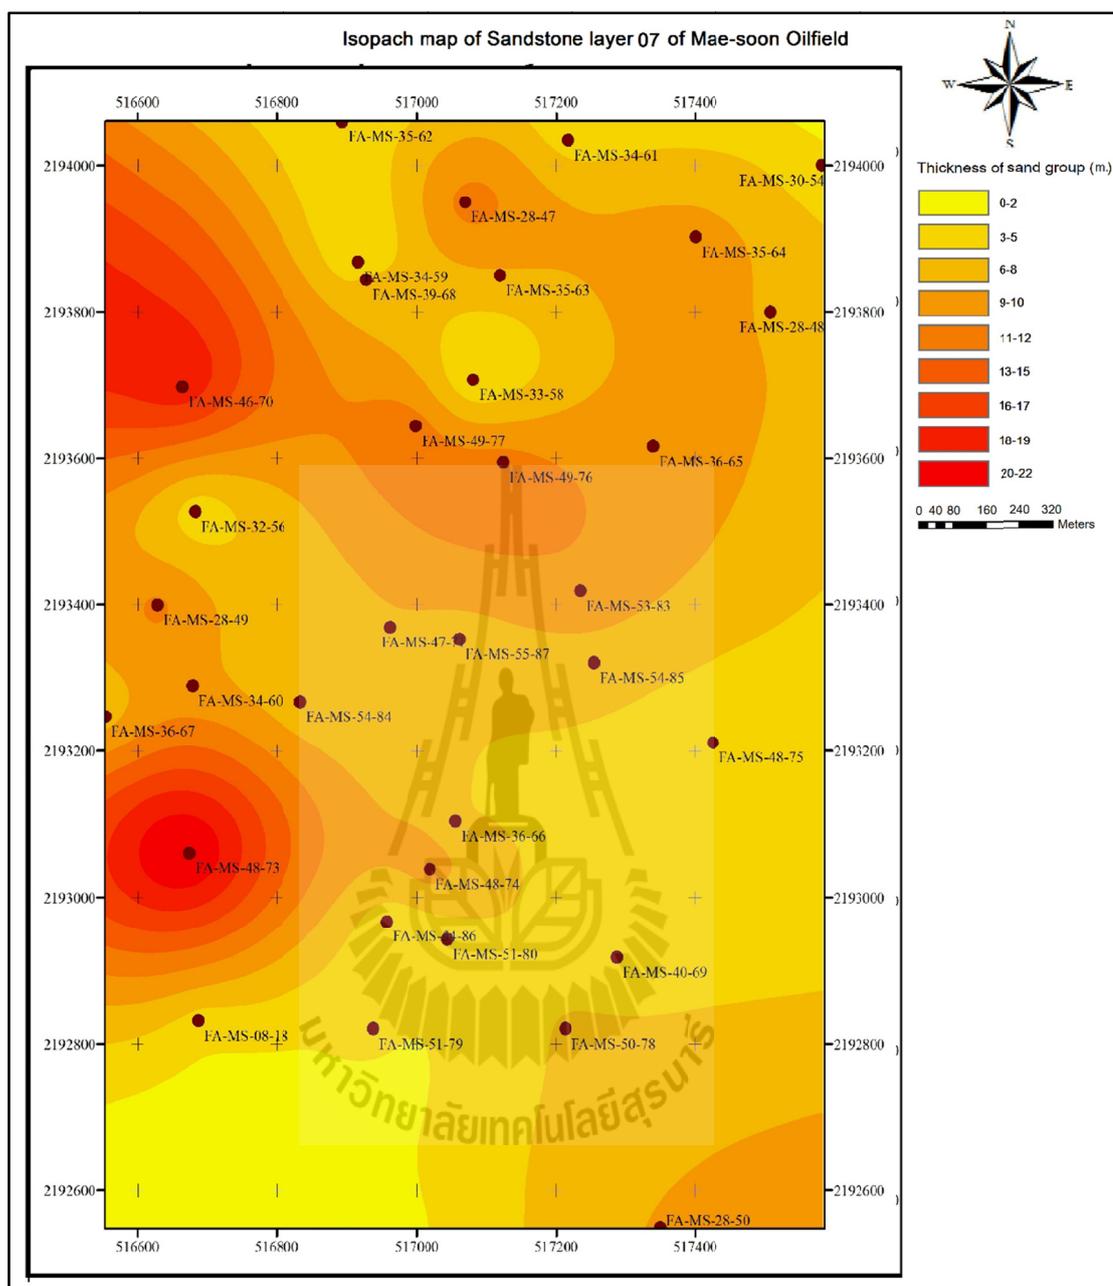

**Figure 4.4** Isopach map of sandstone layer 04 of Mae-Soon oil field.

**Figure 4.5** Isopach map of sandstone layer 05 of Mae-Soon oil field.

**Figure 4.6** Isopach map of sandstone layer 06 of Mae-Soon oil field.

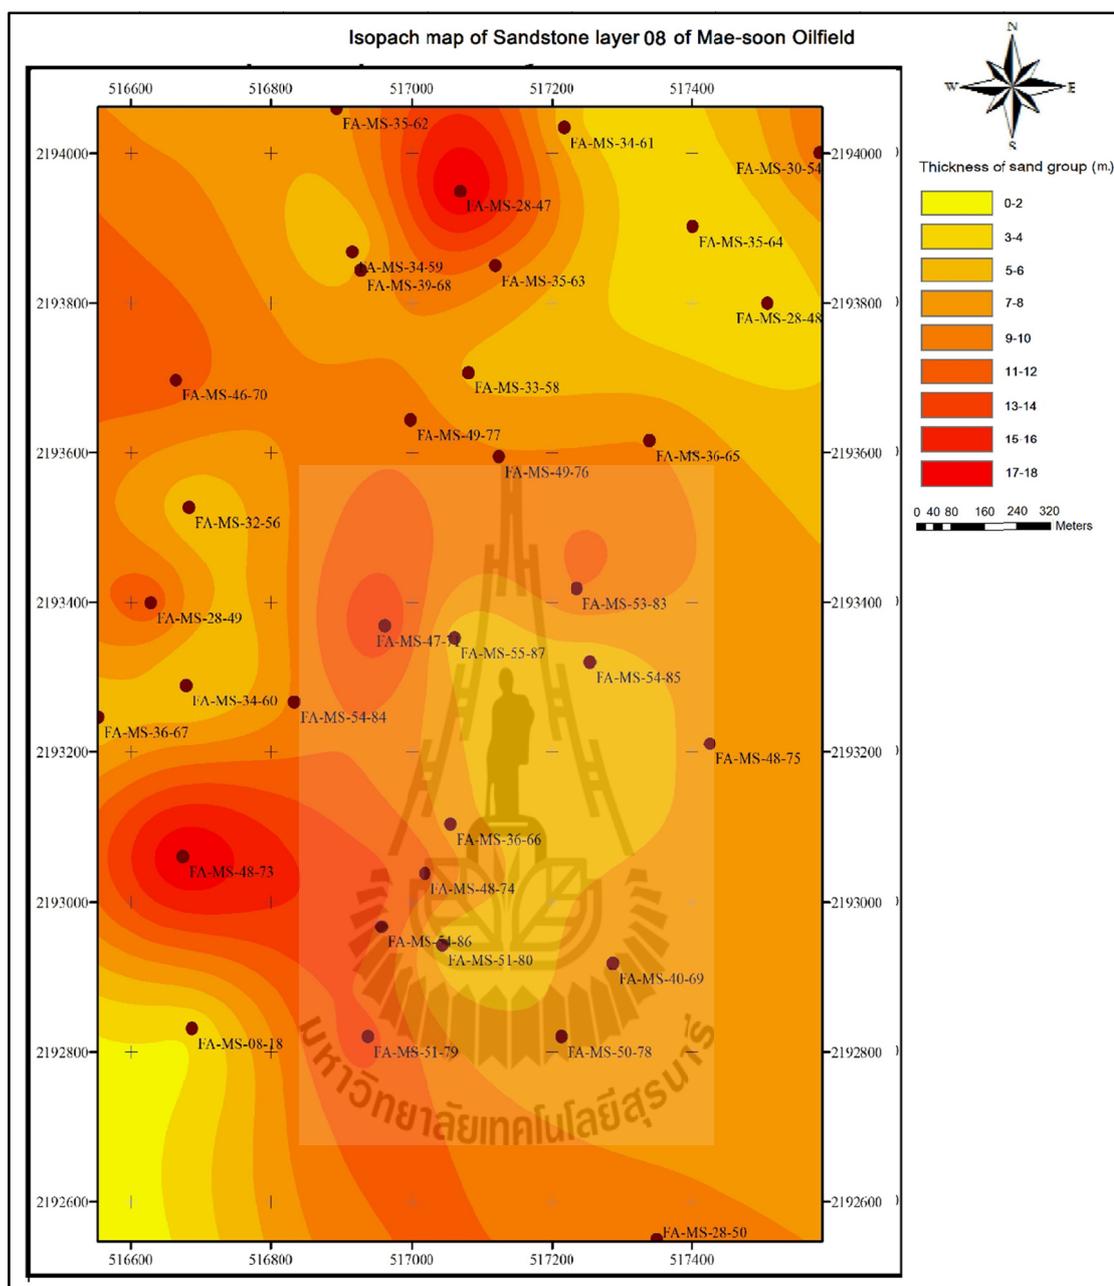

**Figure 4.7** Isopach map of sandstone layer 07 of Mae-Soon oil field.

Figure 4.8 revealed the distribution of thickness of sandstone layer 08 in the study area. This layer is found at depth between 1,972 and 2,340 feet and the thickest (41 feet) is found at well no. FA-MS-28-47 whereas the thinnest layer (4 feet) is found at well no. FA-MS-35-64 and FA-MS-08-18. This sandstone layer is medium sand Lithic Greywacke with an average grain size of 0.2 millimeter. It contains 2% cementing material and 23% Matrix.

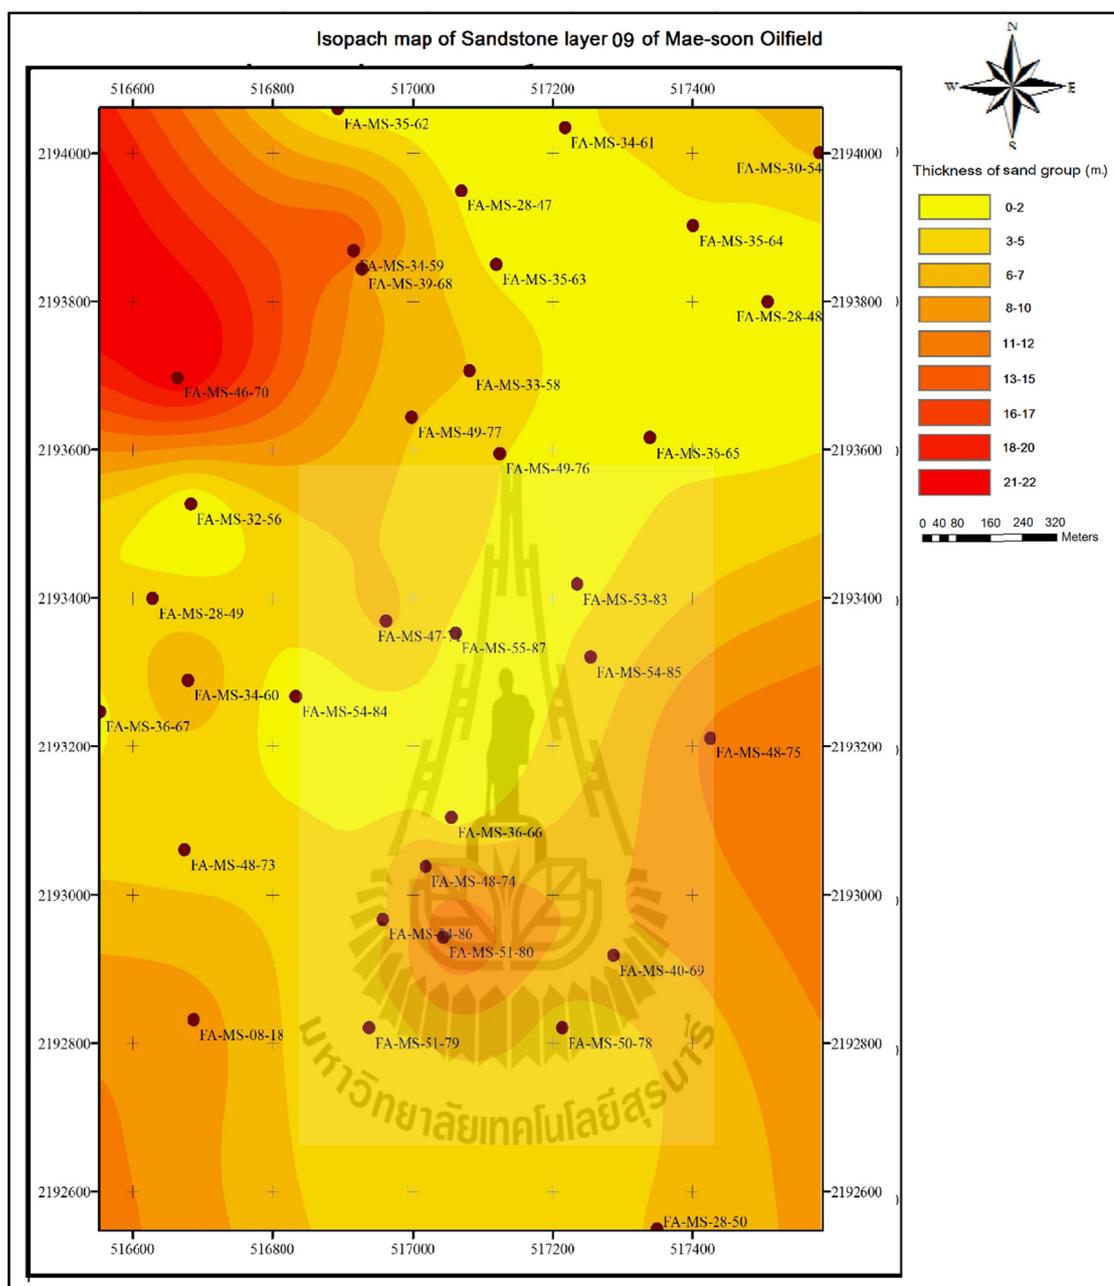

Figure 4.9 revealed the distribution of thickness of sandstone layer 09 in the study area. This layer is found at depth between 2,014 and 2,430 feet and the thickest (72 feet) is found at well no. FA-MS-46-70 whereas the thinnest layer (4 feet) is found at well no. FA-MS-28-48. This sandstone layer is medium sand Lithic Greywacke with an average grain size of 0.27 millimeter. It contains 3% cementing material and 25% Matrix.

Figure 4.10 revealed the distribution of thickness of sandstone layer 10 in the study area. This layer is found at depth between 2,124 and 2,530 feet and the thickest (58 feet) is found at well no. FA-MS-48-75 whereas the thinnest layer (5 feet) is found at well no. FA-MS-35-64. This sandstone layer is medium sand Lithic Greywacke with an average grain size of 0.35 millimeter. It contains 2% cementing material and 16% Matrix.

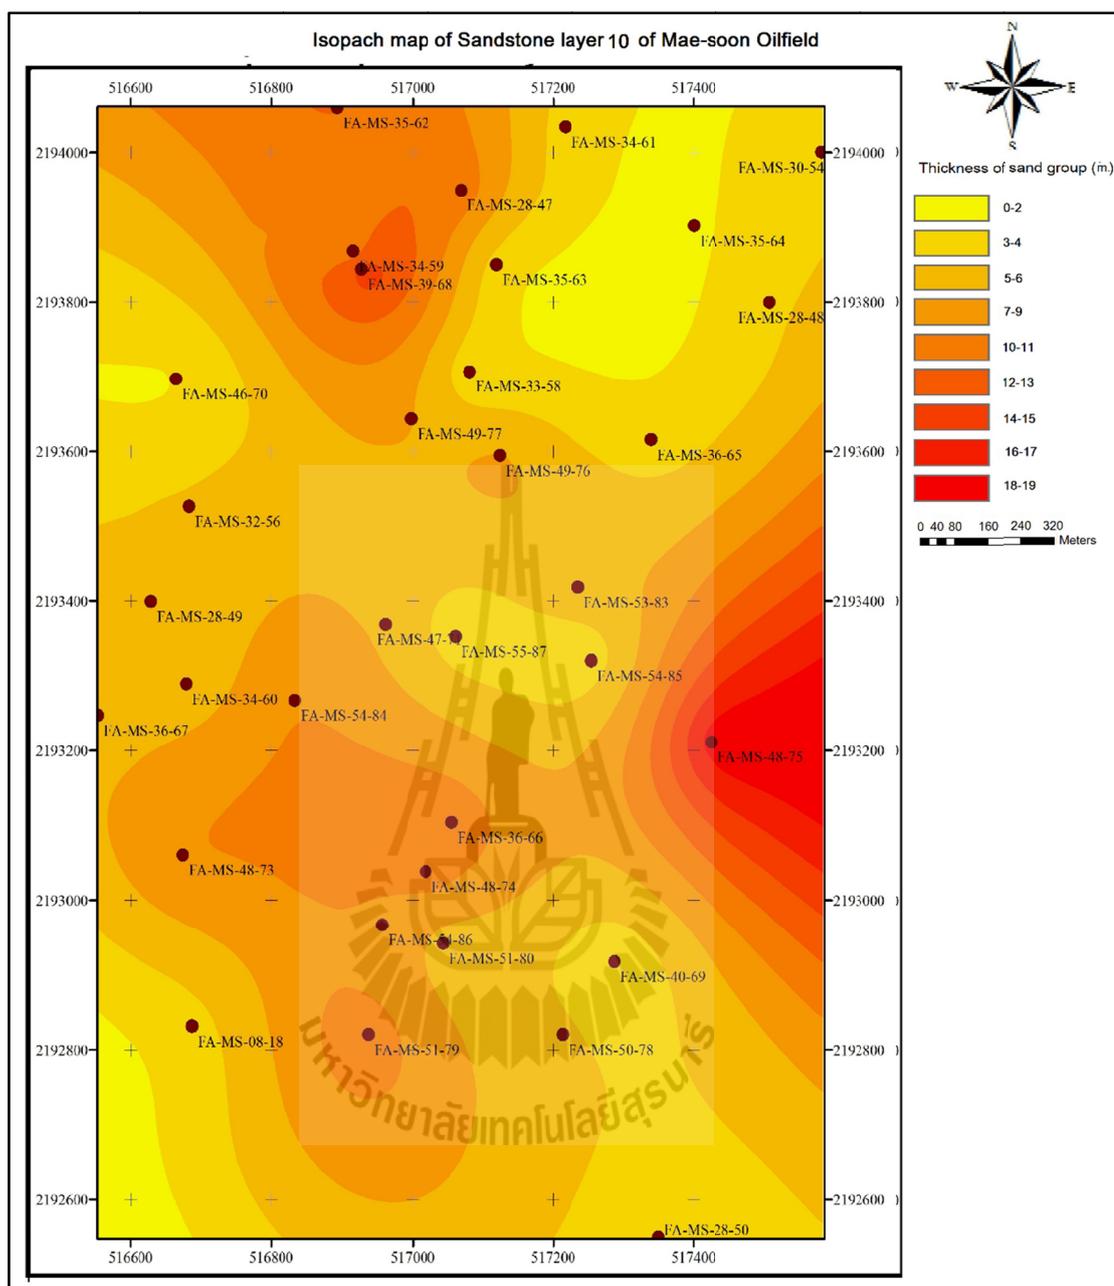

Figure 4.11 revealed the distribution of thickness of sandstone layer 11 in the study area. This layer is found at depth between 2,150 and 2,636 feet and the thickest (52 feet) is found at well no. FA-MS-46-70 whereas the thinnest layer (5 feet) is found at well no. FA-MS-28-48. This sandstone layer is coarse sand Lithic Greywacke with an average grain size of 0.6 millimeter. It contains 2% cementing material and 20% Matrix.

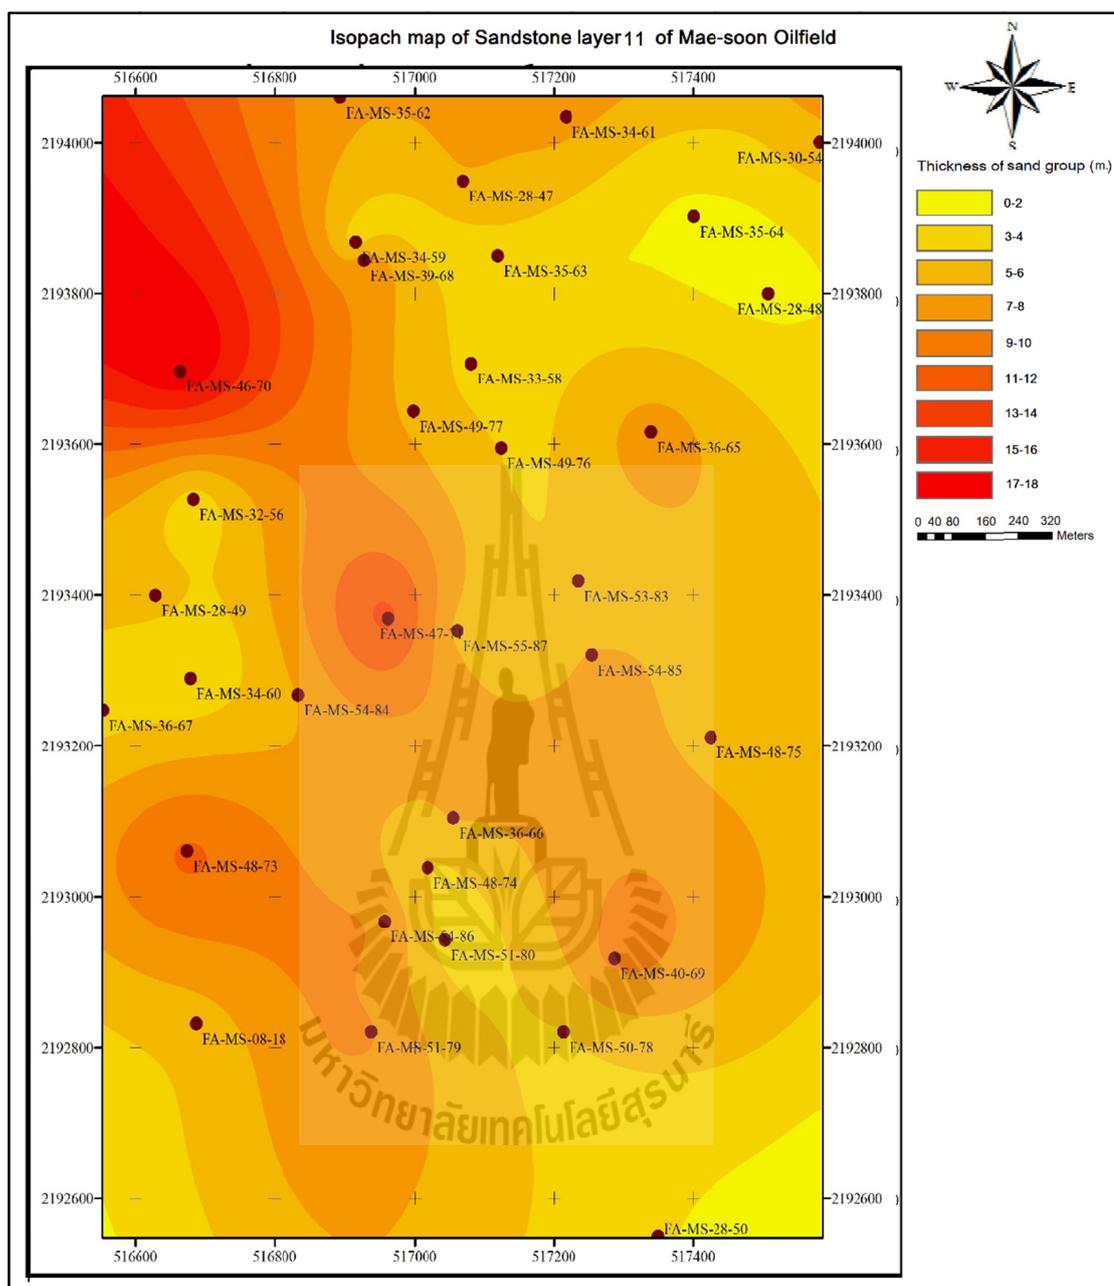

**Figure 4.8** Isopach map of sandstone layer 08 of Mae-Soon oil field.

**Figure 4.9** Isopach map of sandstone layer 09 of Mae-Soon oil field.

**Figure 4.10** Isopach map of sandstone layer 10 of Mae-Soon oil field.

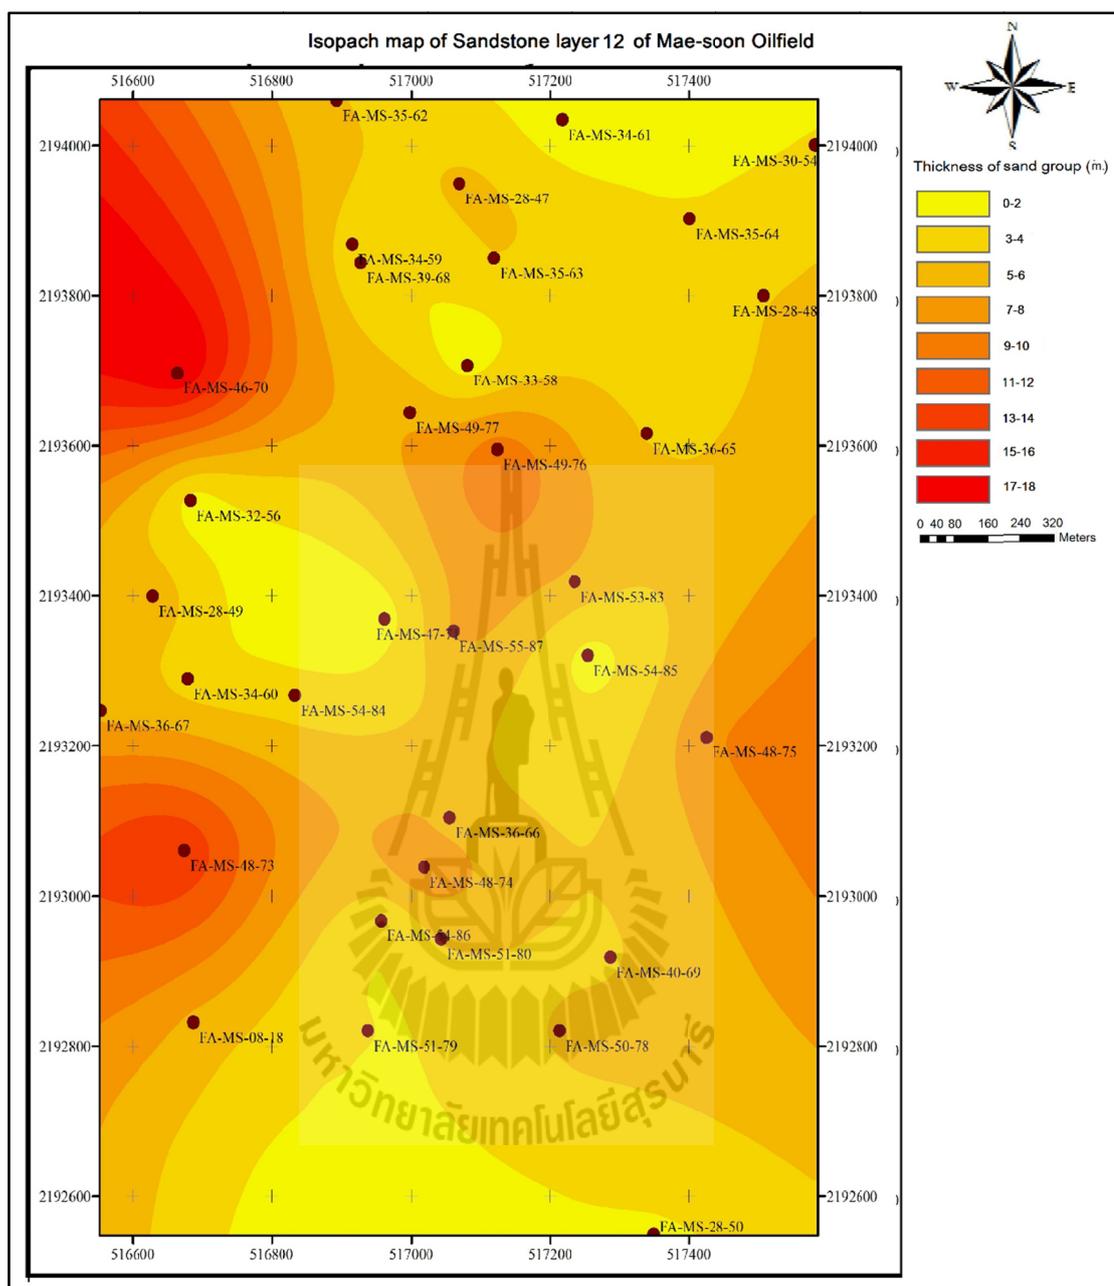

**Figure 4.11** Isopach map of sandstone layer 11 of Mae-Soon oil field.

Figure 4.12 revealed the distribution of thickness of sandstone layer 12 in the study area. This layer is found at depth between 2,248 and 2,688 feet and the thickest (58 feet) is found at well no. FA-MS-46-70 whereas the thinnest layer (5 feet) is found at well no. FA-MS-34-61. This sandstone layer is coarse sand Lithic Greywacke with an average grain size of 0.8 millimeter. It contains 3% cementing material and 19% Matrix.

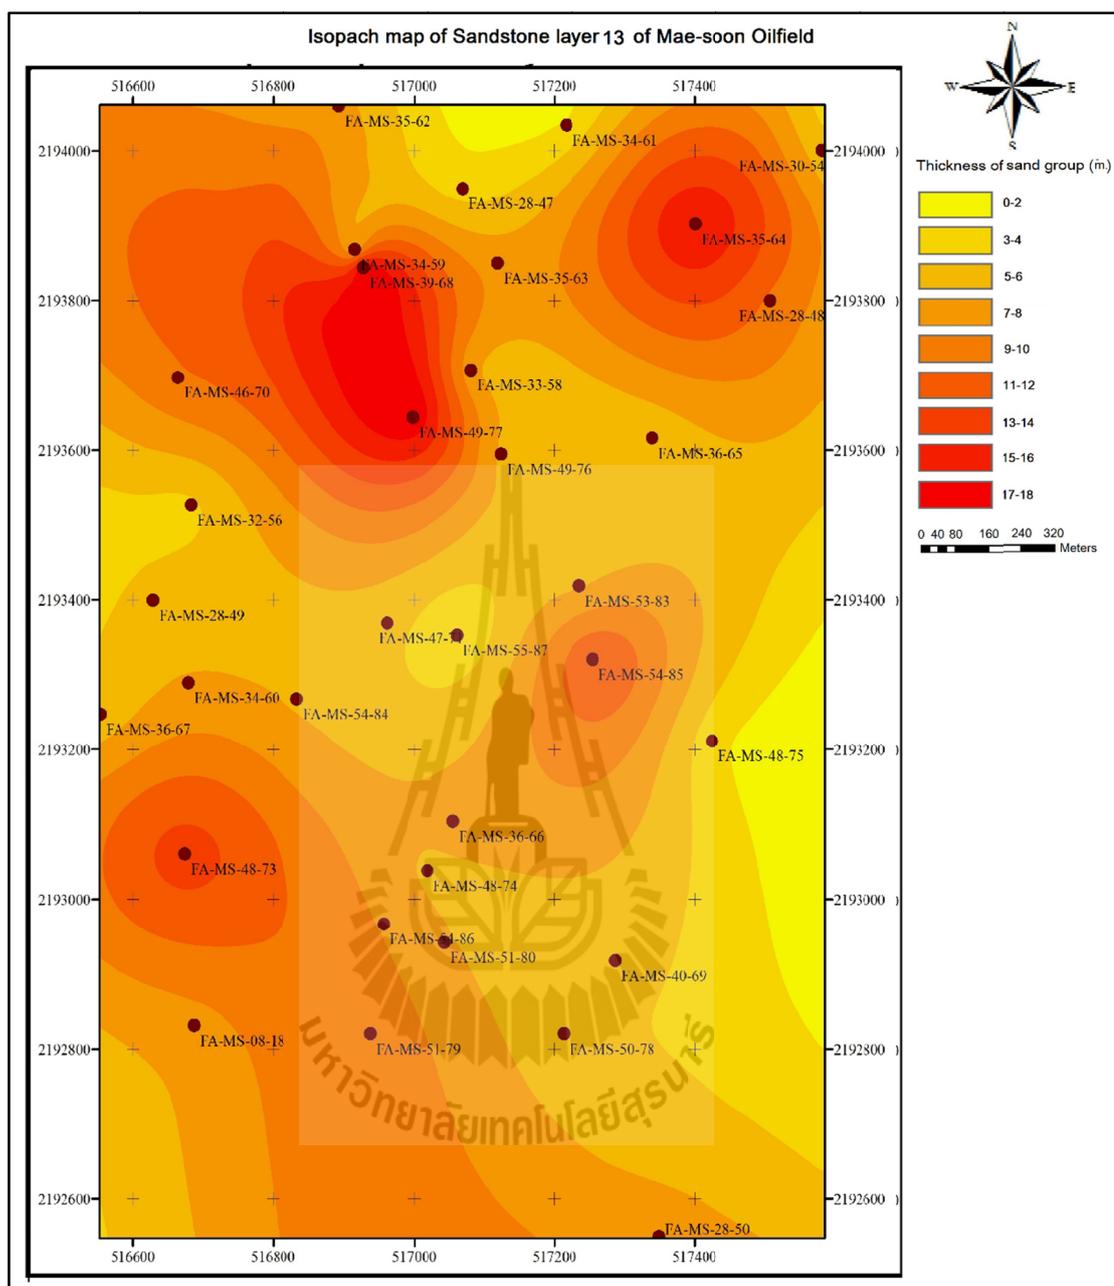

Figure 4.13 revealed the distribution of thickness of sandstone layer 13 in the study area. This layer is found at depth between 2,322 and 2,735 feet and the thickest (38 feet) is found at well no. FA-MS-39-68 whereas the thinnest layer (5 feet) is found at well no. FA-MS-34-61. This sandstone layer is very fine sand Quartz Greywacke with an average grain size of 0.07 millimeter. It contains 3% cementing material and 22% Matrix.

Figure 4.14 revealed the distribution of thickness of sandstone layer 14 in the study area. This layer is found at depth between 2,410 and 2,800 feet and the thickest (38 feet) is found at well no. FA-MS-39-68 whereas the thinnest layer (5 feet) is found at well no. FA-MS-34-61. This sandstone layer is very fine sand Quartz Greywacke with an average grain size of 0.09 millimeter. It contains 2% cementing material and 23% Matrix.

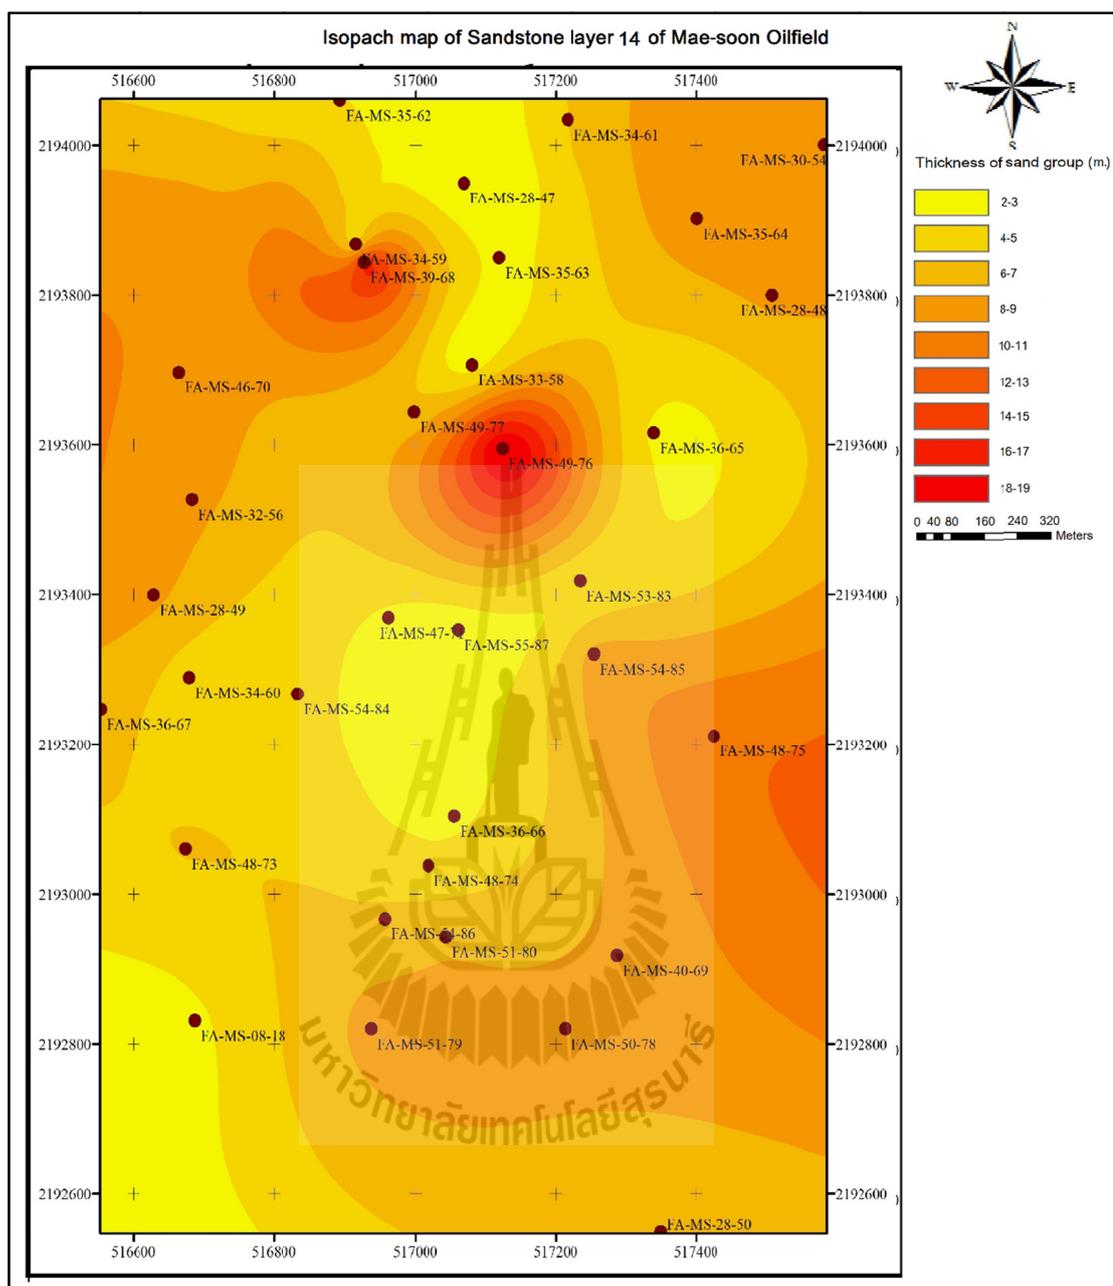

Figure 4.15 revealed the distribution of thickness of sandstone layer 15 in the study area. This layer is found at depth between 2,456 and 2,879 feet and the thickest (36 feet) is found at well no. FA-MS-39-68 whereas the thinnest layer (4 feet) is found at well no. FA-MS-28-50. This sandstone layer is very fine sand Quartz Greywacke with an average grain size of 0.125 millimeter. It contains 2% cementing material and 20% Matrix.

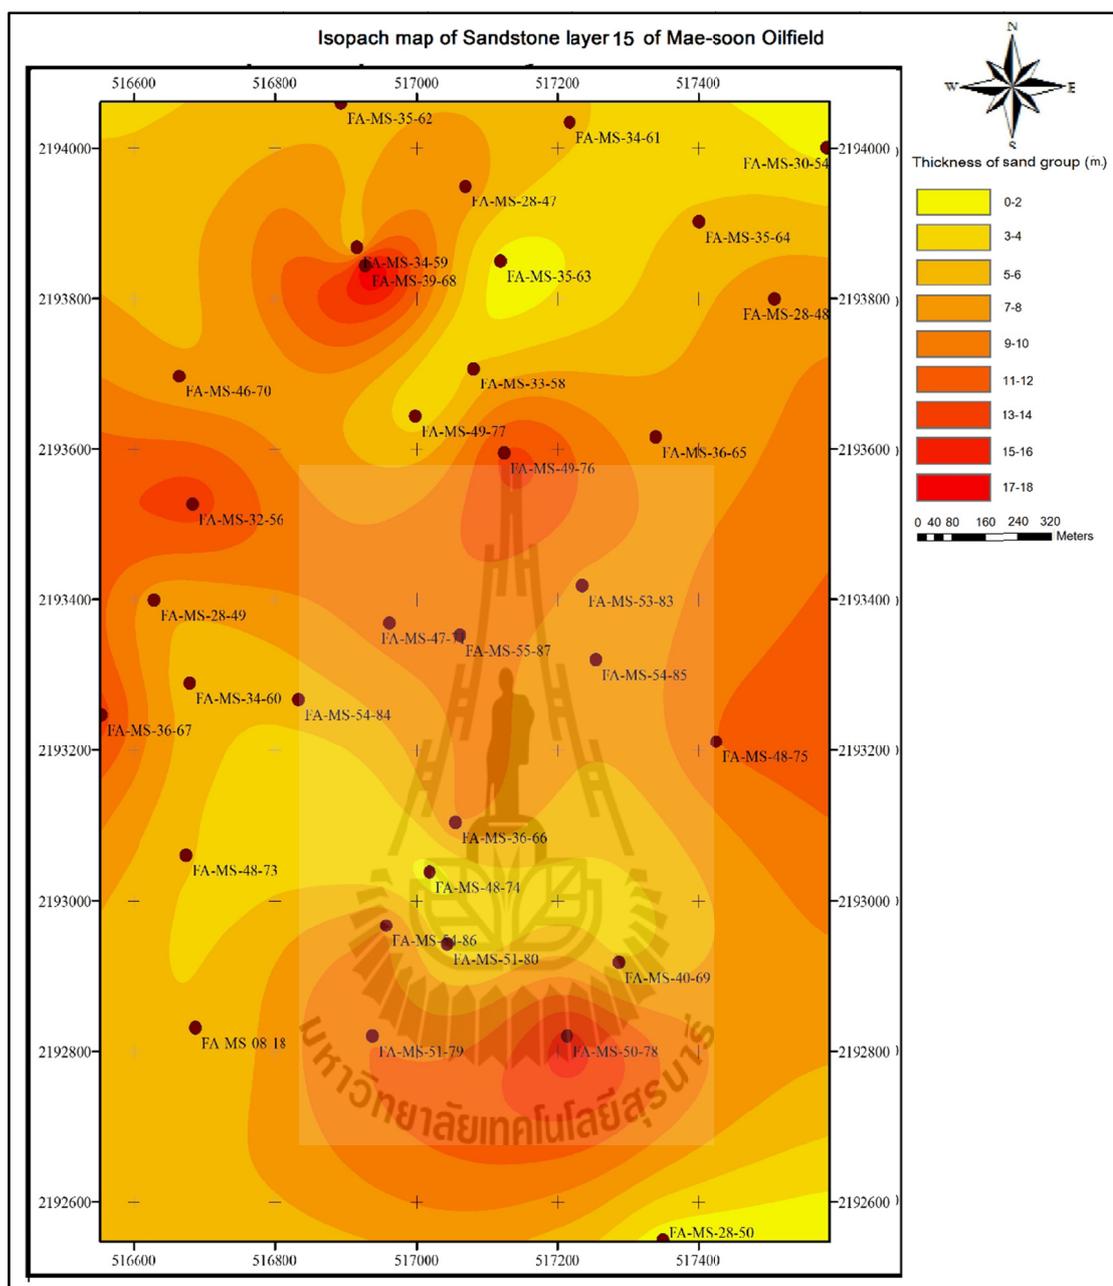

**Figure 4.12** Isopach map of sandstone layer 12 of Mae-Soon oil field.

**Figure 4.13** Isopach map of sandstone layer 13 of Mae-Soon oil field.

**Figure 4.14** Isopach map of sandstone layer 14 of Mae-Soon oil field.

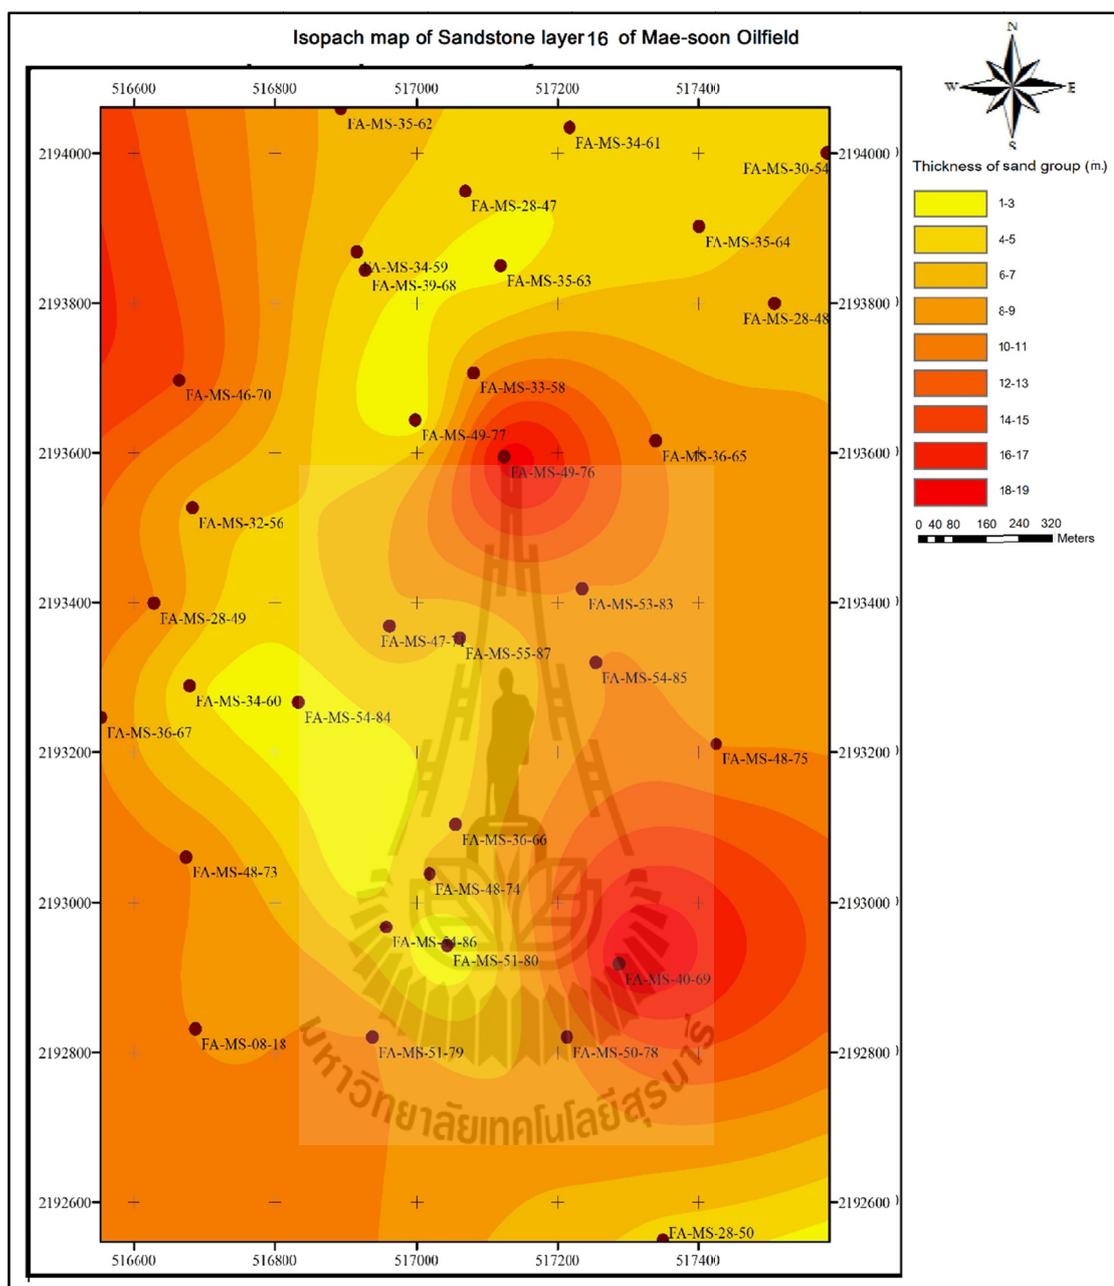

**Figure 4.15** Isopach map of sandstone layer 15 of Mae-Soon oil field.

Figure 4.16 revealed the distribution of thickness of sandstone layer 16 in the study area. This layer is found at depth between 2,534 and 2,970 feet and the thickest (40 feet) is found at well no. FA-MS-40-69 whereas the thinnest layer (4 feet) is found at well no. FA-MS-51-80. This sandstone layer is fine sand Quartz Greywacke with an average grain size of 0.15 millimeter. It contains 3% cementing material and 22% Matrix.

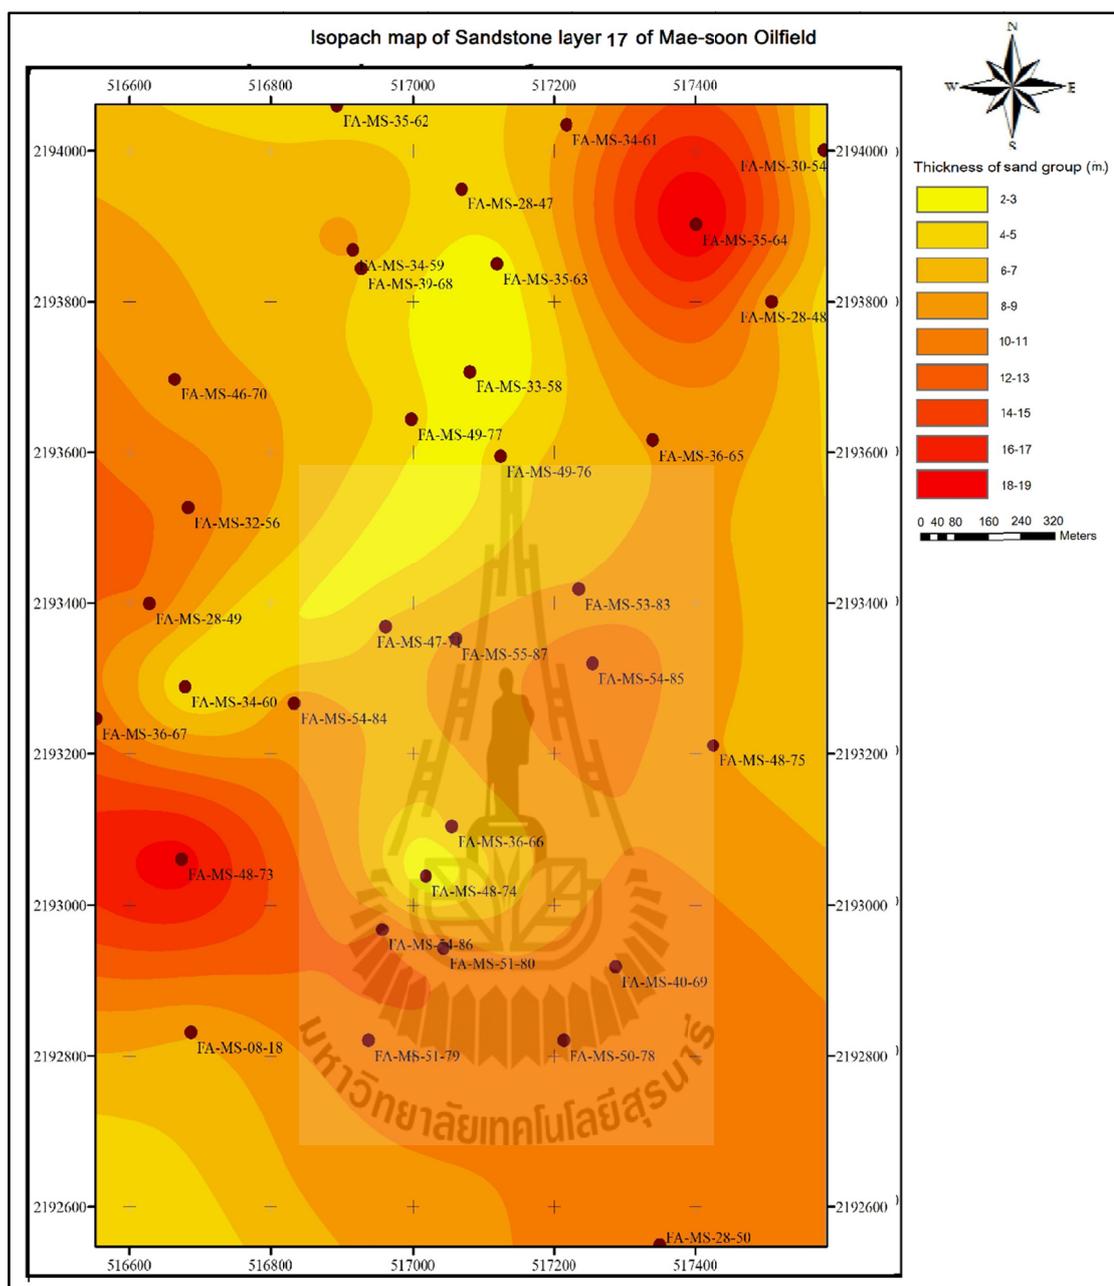

Figure 4.17 revealed the distribution of thickness of sandstone layer 17 in the study area. This layer is found at depth between 2,628 and 3,110 feet and the thickest (34 feet) is found at well no. FA-MS-35-64 whereas the thinnest layer (5 feet) is found at well no. FA-MS-33-58. This sandstone layer is fine sand Quartz Greywacke with an average grain size of 0.17 millimeter. It contains 2% cementing material and 25% Matrix.

Figure 4.18 revealed the distribution of thickness of sandstone layer 18 in the study area. This layer is found at depth between 2,704 and 3,312 feet and the thickest (32 feet) is found at well no. FA-MS-48-73 whereas the thinnest layer (5 feet) is found at well no. FA-MS-28-47. This sandstone layer is medium sand Quartz Greywacke with an average grain size of 0.25 millimeter. It contains 4% cementing material and 21% Matrix.

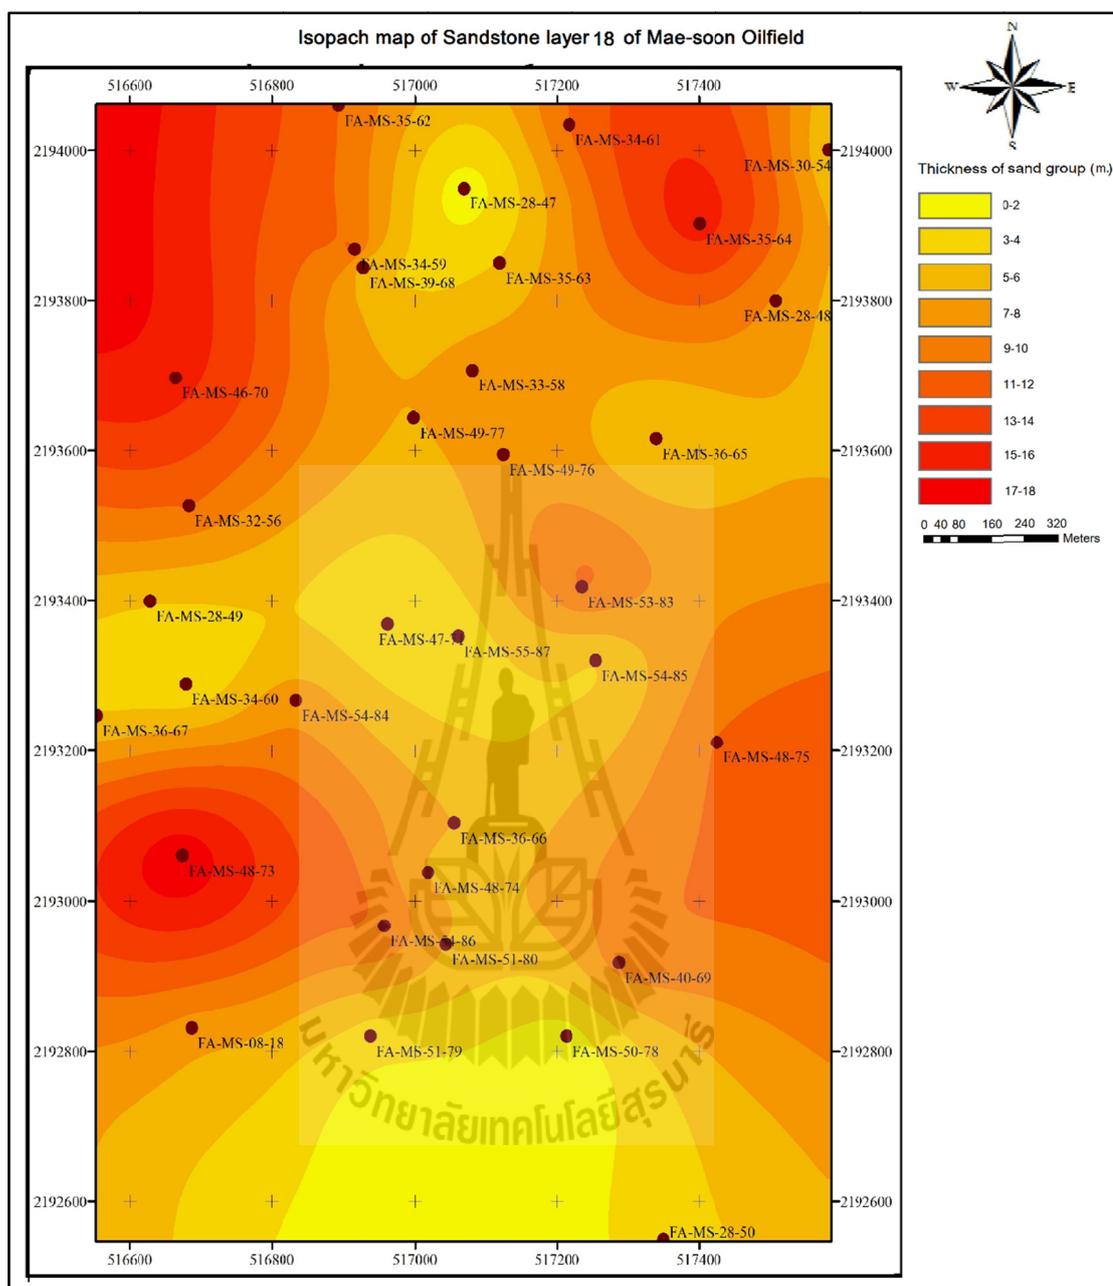

Figure 4.19 revealed the distribution of thickness of sandstone layer 19 in the study area. This layer is found at depth between 2,815 and 3,434 feet and the thickest (32 feet) is found at well no. FA-MS-40-70 whereas the thinnest layer (5 feet) is found at well no. FA-MS-51-80. This sandstone layer is medium sand Quartz Greywacke with an average grain size of 0.4 millimeter. It contains 3% cementing material and 22% Matrix.

## **4.2 Stratigraphic section**

Results from wireline log interpretation together with some other informative geological data, e.g. mud log data and seismic data, which were reviewed at the first step of the study, could be used to generate stratigraphic section of the 33 boreholes of Mae-Soon oil field. Consequently, the stratigraphic section of 33 boreholes can be generated as depicted in Figure 4.20 to Figure 4.52, respectively.

## **4.3 Potential reservoir rock properties**

### **4.3.1 Porosity and permeability**

Results from porosity and permeability calculation together with well name, depth of collected core samples, sandstone type, average grain size (mm), cementing material (percent) and matrix (percent) of all 19 potential sandstone reservoirs of Mae-Soon oil field are concluded and depicted in Appendix C

To illustrate the porosity quality distribution of all 19 potential sandstone reservoirs, all available porosity data both from direct measuring in laboratory and from wireline log calculation were plotted and showed in Figure 4.53. It was found that most of sandstone shows fair to medium porosity quality according to Muskat (1949) and Dickker (1985) classification and showed in Figure 4.54.

Figure 4.55 illustrates the distribution of permeability (milliDarcy), depth (meter), average grain size (millimeter), cementing material (percent) and matrix (percent) data of all 19 potential sandstone reservoirs of Mae-Soon oil field, respectively.

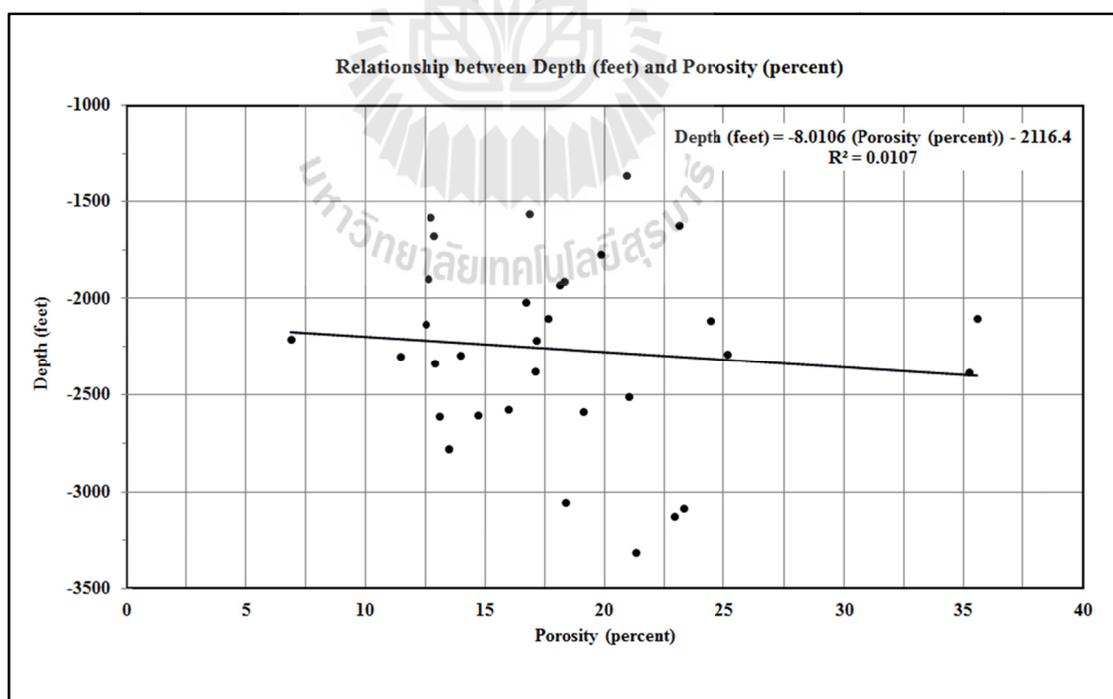

**Figure 4.55** Distribution of Permeability, Depth, Grain size, Cementing material and Matrix of 19 sandstone layers of Mae-Soon oil field.

Consequently, the results of porosity and permeability analysis in order to evaluate the ability of 19 sandstone layers of Mae-Soon oil field indicate that these sandstones have capable to store hydrocarbon according to Muskat (1949) and Dickker (1985) classification.

#### 4.3.2 The relationship between rock properties and depth

In general porosity is inversely proportional to depth. Therefore, the relationship between porosity and depth can be determined by cross-plotting these two parameters. Figure 4.56 illustrates the relationship between depth and porosity of the all 19 sandstone layers of Mae-Soon oil field. It is found that porosity is related to depth by the following equation;

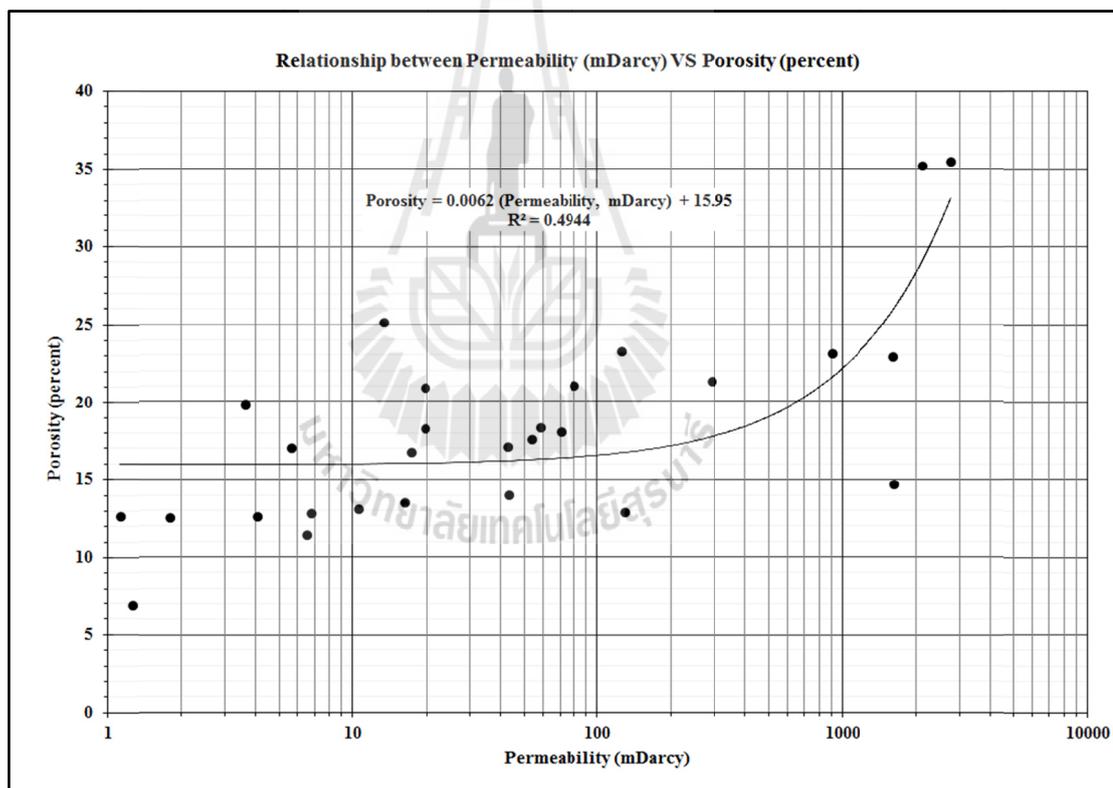

$$\text{Depth (feet)} = -8.0106 (\text{Porosity (percent)}) - 2116.4 \quad (4.1)$$

**Figure 4.56** Cross-plot between porosity and depth of sandstone of Mae-Soon oil field.

Unlike the relationship between depth and porosity, permeability is directly proportional to porosity. However, the relationship between permeability and porosity can also be determined by cross-plotting these two parameters as well. Figure 4.57 shows the relationship between permeability and porosity of the all 19 sandstone layers of Mae-Soon oil field and it is found that permeability is related to porosity by the following equation;

$$\text{Porosity} = 0.0062 (\text{Permeability, mDarcy}) + 15.95 \quad (4.2)$$

**Figure 4.57** Cross-plot between porosity and permeability of sandstone of Mae-Soon oil field.

### **4.3.3 Grouped sandstone layers thickness, porosity, permeability and hydrocarbon saturation map**

Based on lithology and petrophysical properties, including porosity and permeability, potential oil sandstone reservoirs of Mae-Soon oil field could be divided into 3 groups as follows.

Group A: sandstone layer 1 to 6

Group B: sandstone layer 7 to 13

Group C: sandstone layer 14 to 19

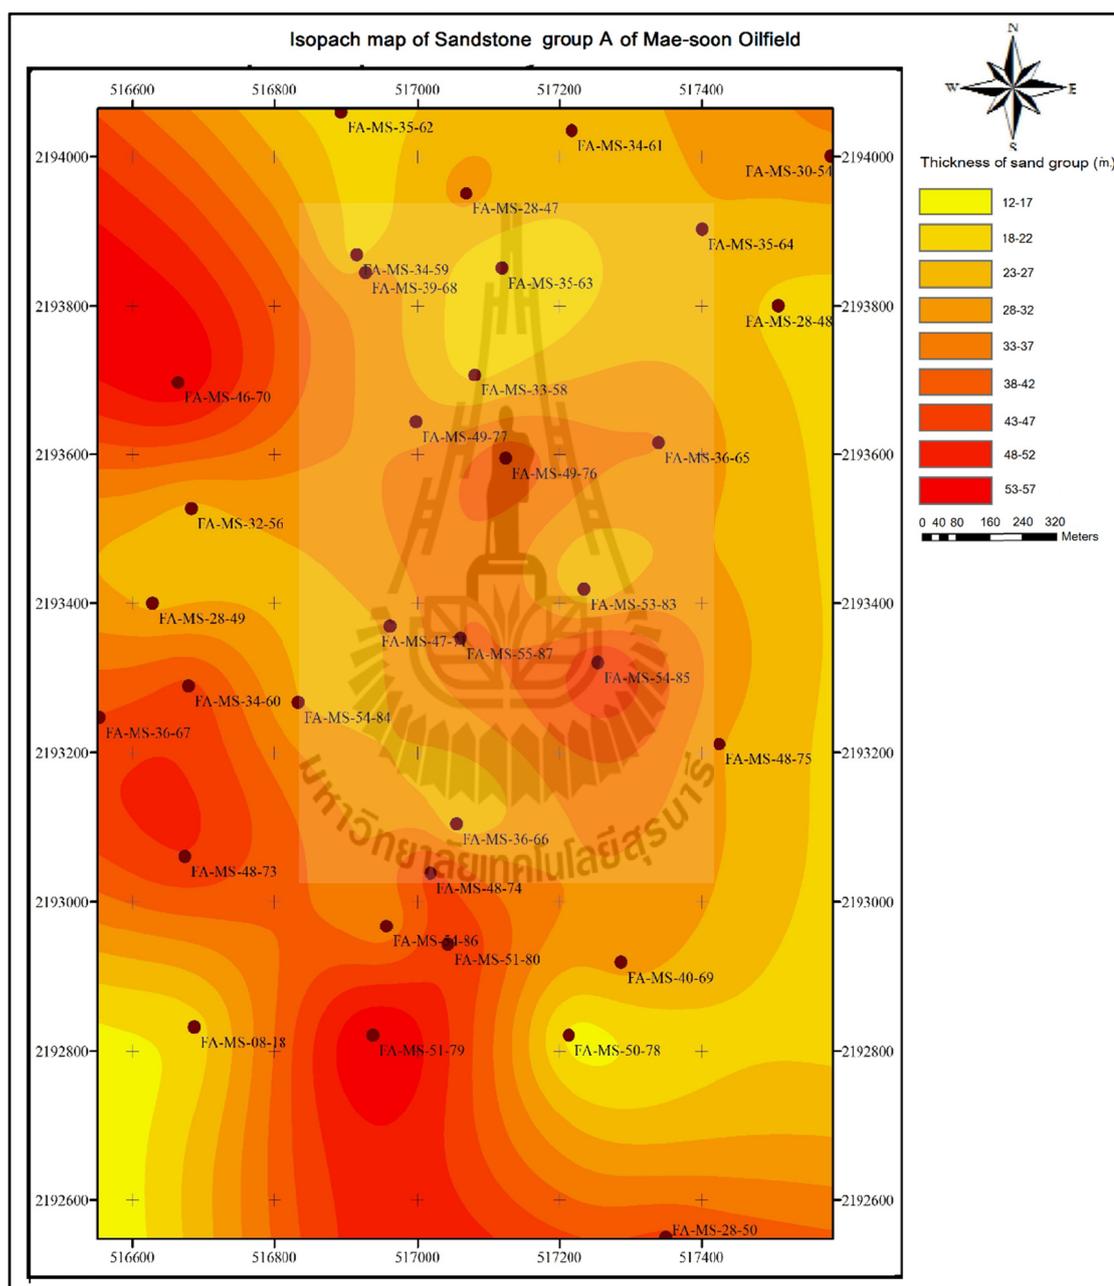

Consequently isopach, porosity, permeability, and hydrocarbon saturation distribution map of each sandstone group could be generated as presented in the Figure 4.58 to Figure 4.69, respectively.

Sandstone Group A of Mae-Soon oil field was found at depth 1,295-2,140 feet. It has the thickest layer of about 180 feet and the thinnest layer of about 54 feet. The thick sandstone layer appears mostly on the west side of the study area whereas the east side shows lower thickness. This sandstone is Lithic Greywacke type which is composed of very fine to medium-grained sand. The accumulation is fining upward (Figure 4.58).

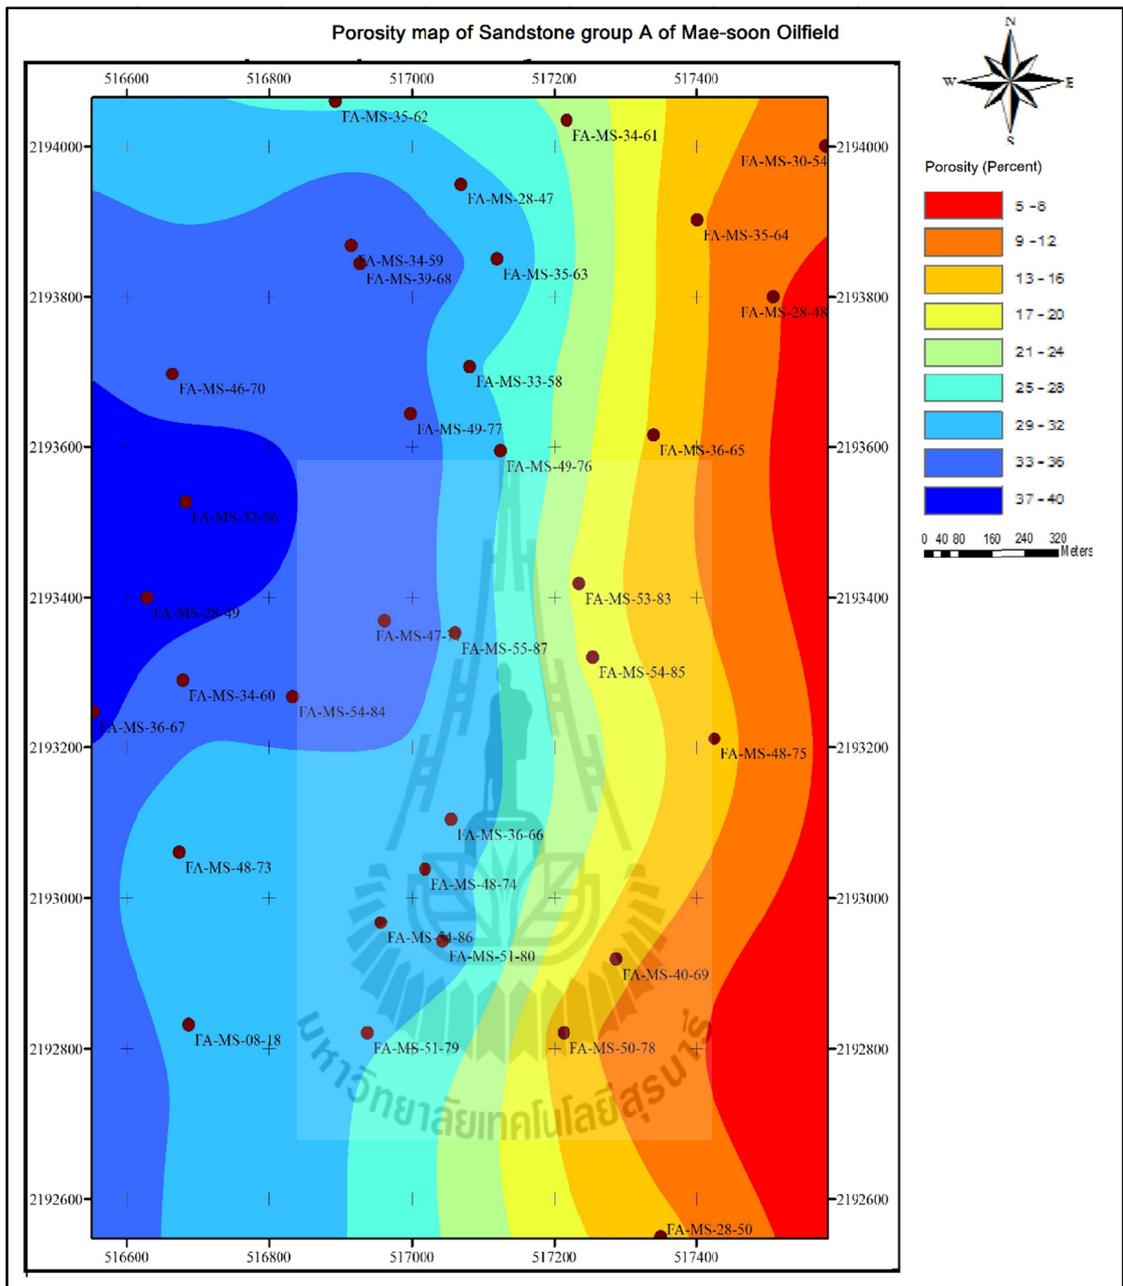

Porosity of sandstone Group A of Mae-Soon oil field is good - very good with an average porosity of 28.05%. The high porosity zone appears at the west of study area and gradually decreases to the east (Figure 4.59).

Permeability of sandstone Group A is fair – good with an average permeability of 466.62 milliDarcy. High permeability appears at the middle-west of the study area and gradually decrease to the east, the north and the south (Figure 4.60).

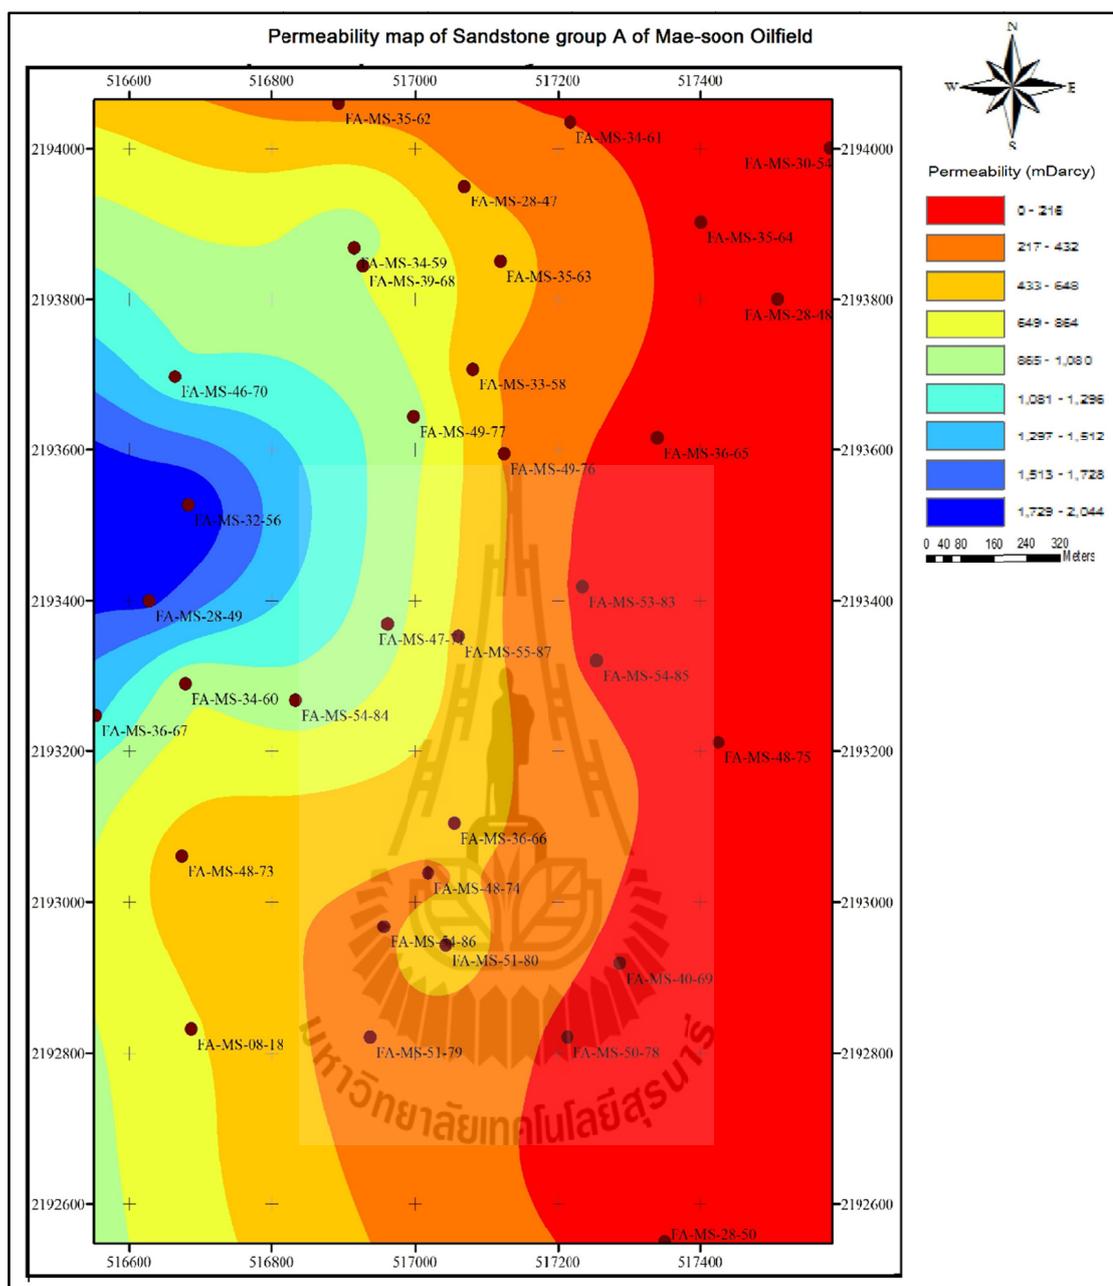

Hydrocarbon saturation of sandstone Group A is good - very good with an average of 0.55. High hydrocarbon saturation appears at the west side of the study area and gradually decreases to the east (Figure 4.61).

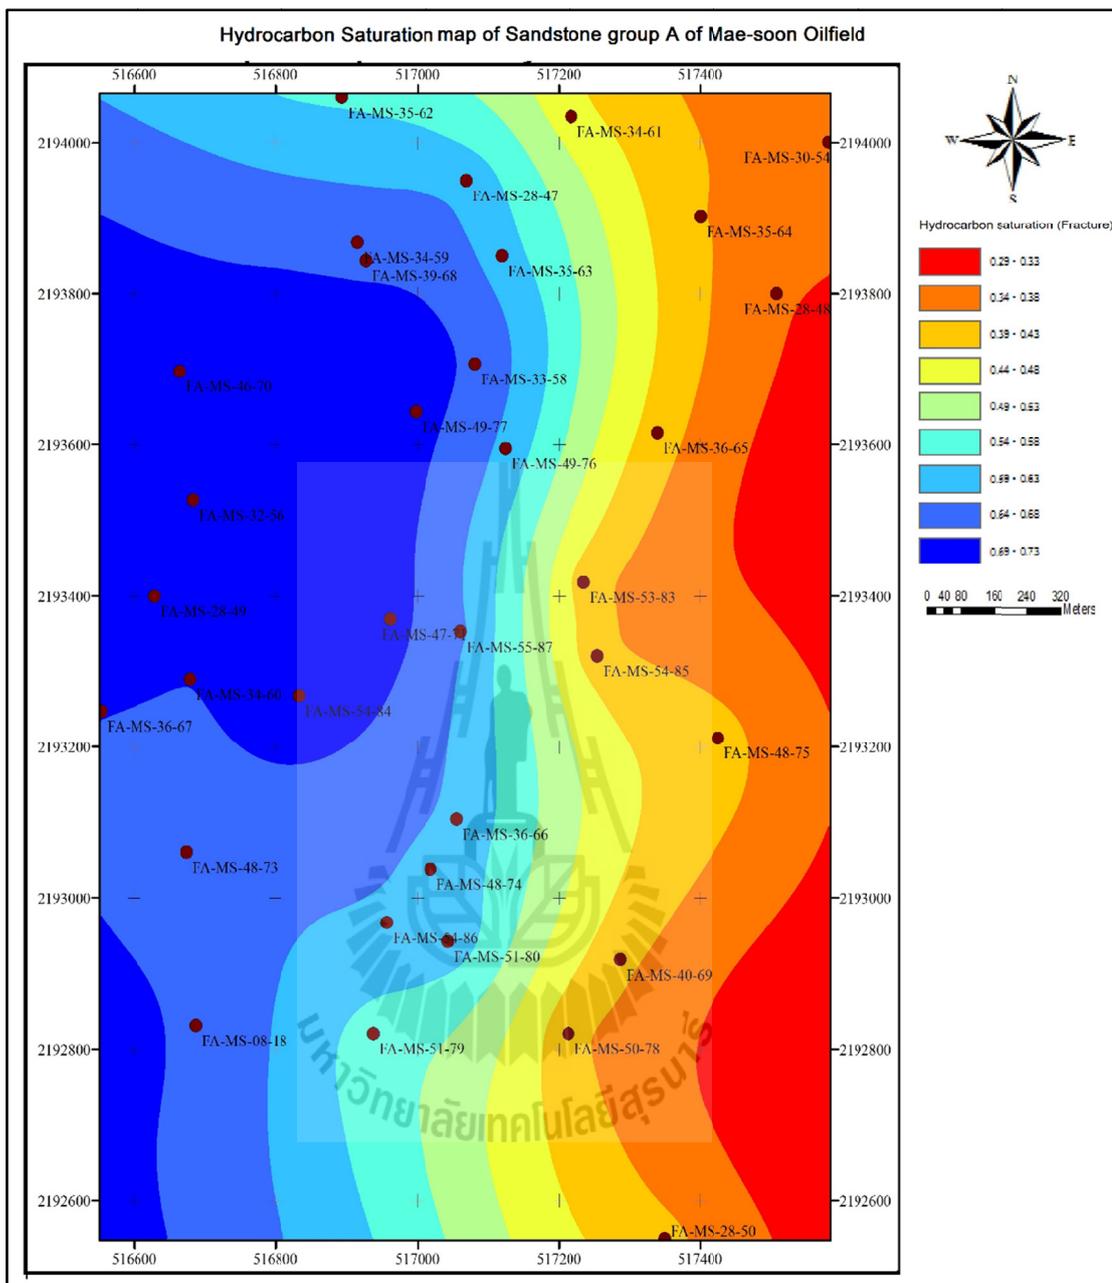

**Figure 4.58** Isopach map of sandstone Group A of Mae-Soon oil field.

**Figure 4.59** Porosity distribution map of sandstone Group A.

**Figure 4.60** Permeability distribution map of sandstone Group A.

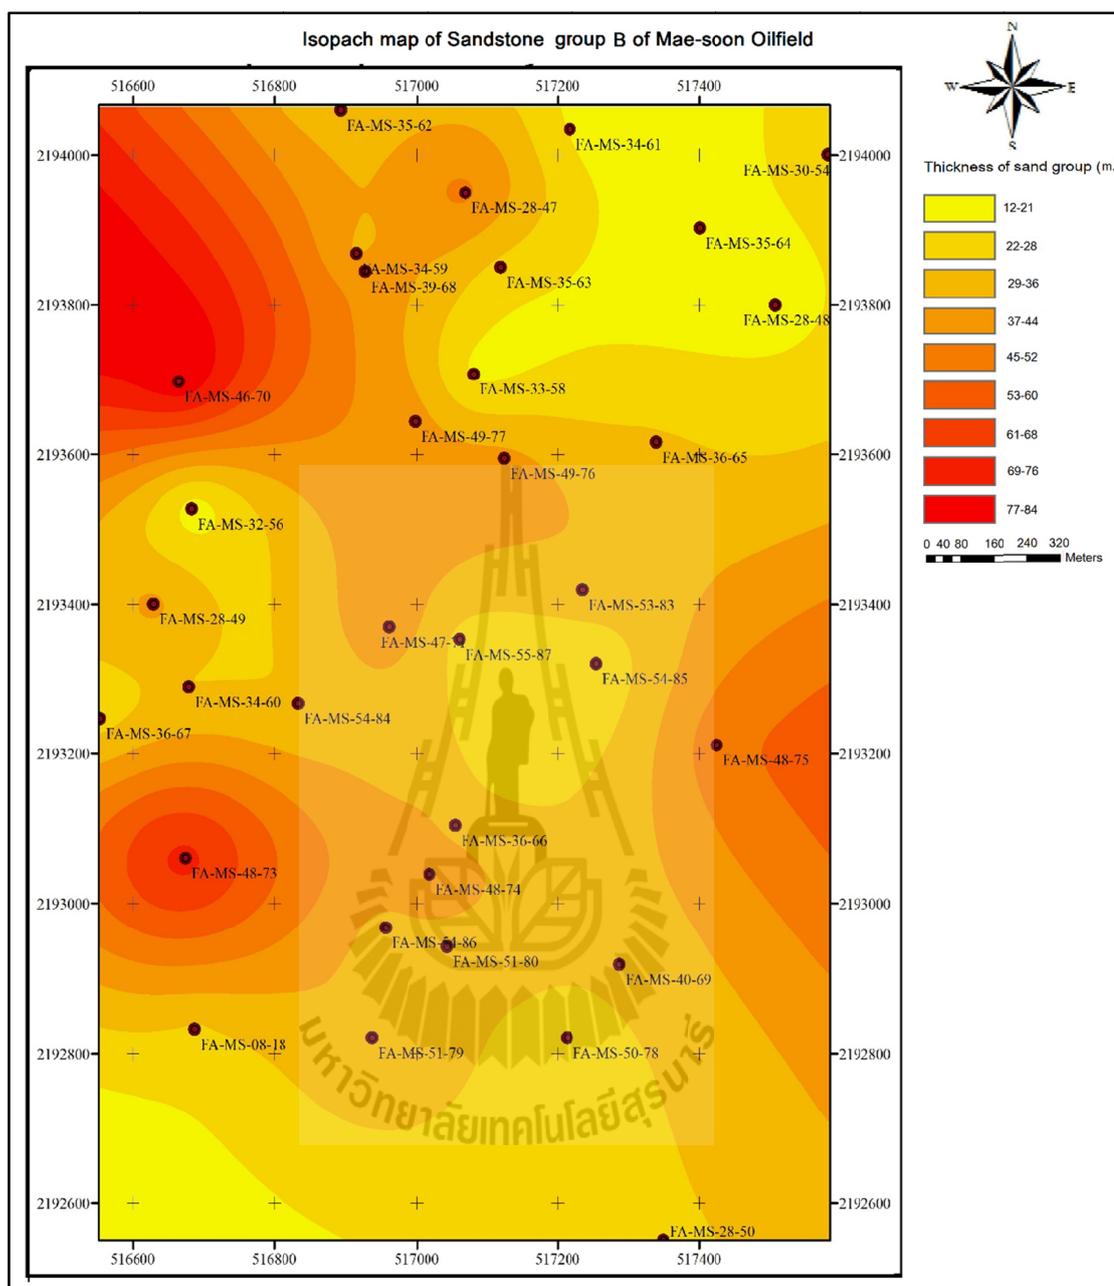

**Figure 4.61** Hydrocarbon saturation distribution map of sandstone Group A.

Sandstone Group B of Mae-Soon oil field was found at depth 1,868-2,680 feet. It has the thickest layer of about 270 feet and the thinnest layer of about 57 feet. The thick sandstone layer appears mostly on the north-west side of the study area whereas the lower thickness shows mostly in the central part of the study area. This sandstone is Lithic Greywacke type which is composed of fine to coarse-grained sand. The accumulation is fining upward (Figure 4.62).

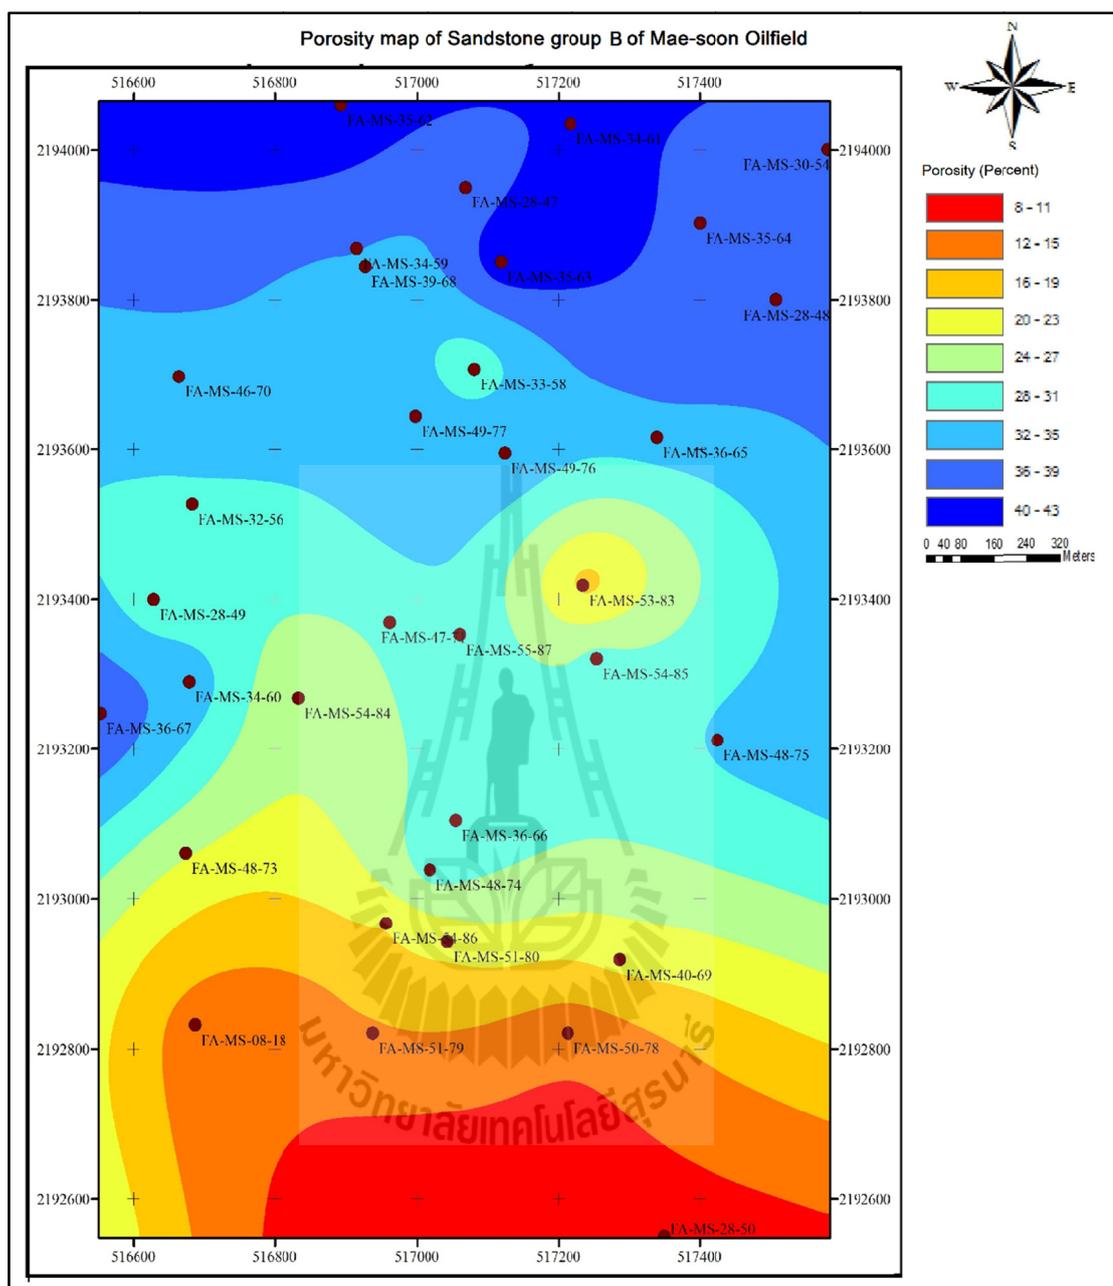

Porosity of sandstone Group B of Mae-Soon oil field is good - very good with an average porosity of 30.77%. The high porosity zone appears at the northern part of study area and gradually decreases to the south (Figure 4.63).

Permeability of sandstone Group B is fair – good with an average permeability of 492.04 milliDarcy. Like porosity, high permeability zone appears at the northern part of the study area and gradually decrease to the south (Figure 4.64).

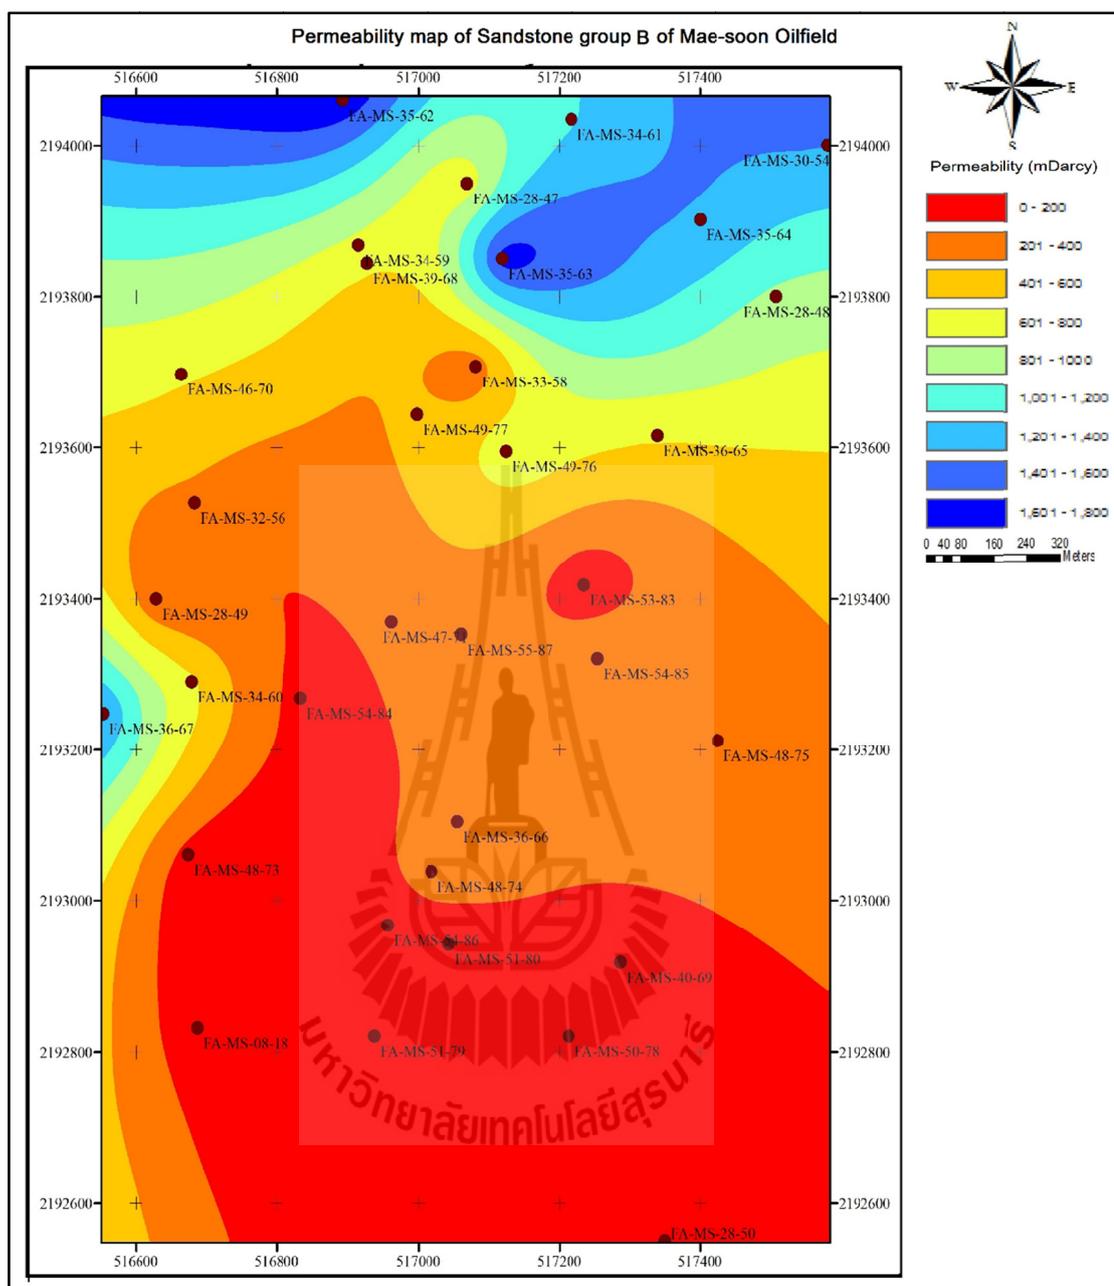

Hydrocarbon saturation of sandstone Group B is good - very good with an average of 0.52. Conforming to porosity and permeability, high hydrocarbon saturation zone appears at the northern part of the study area and gradually decreases to the south (Figure 4.65).

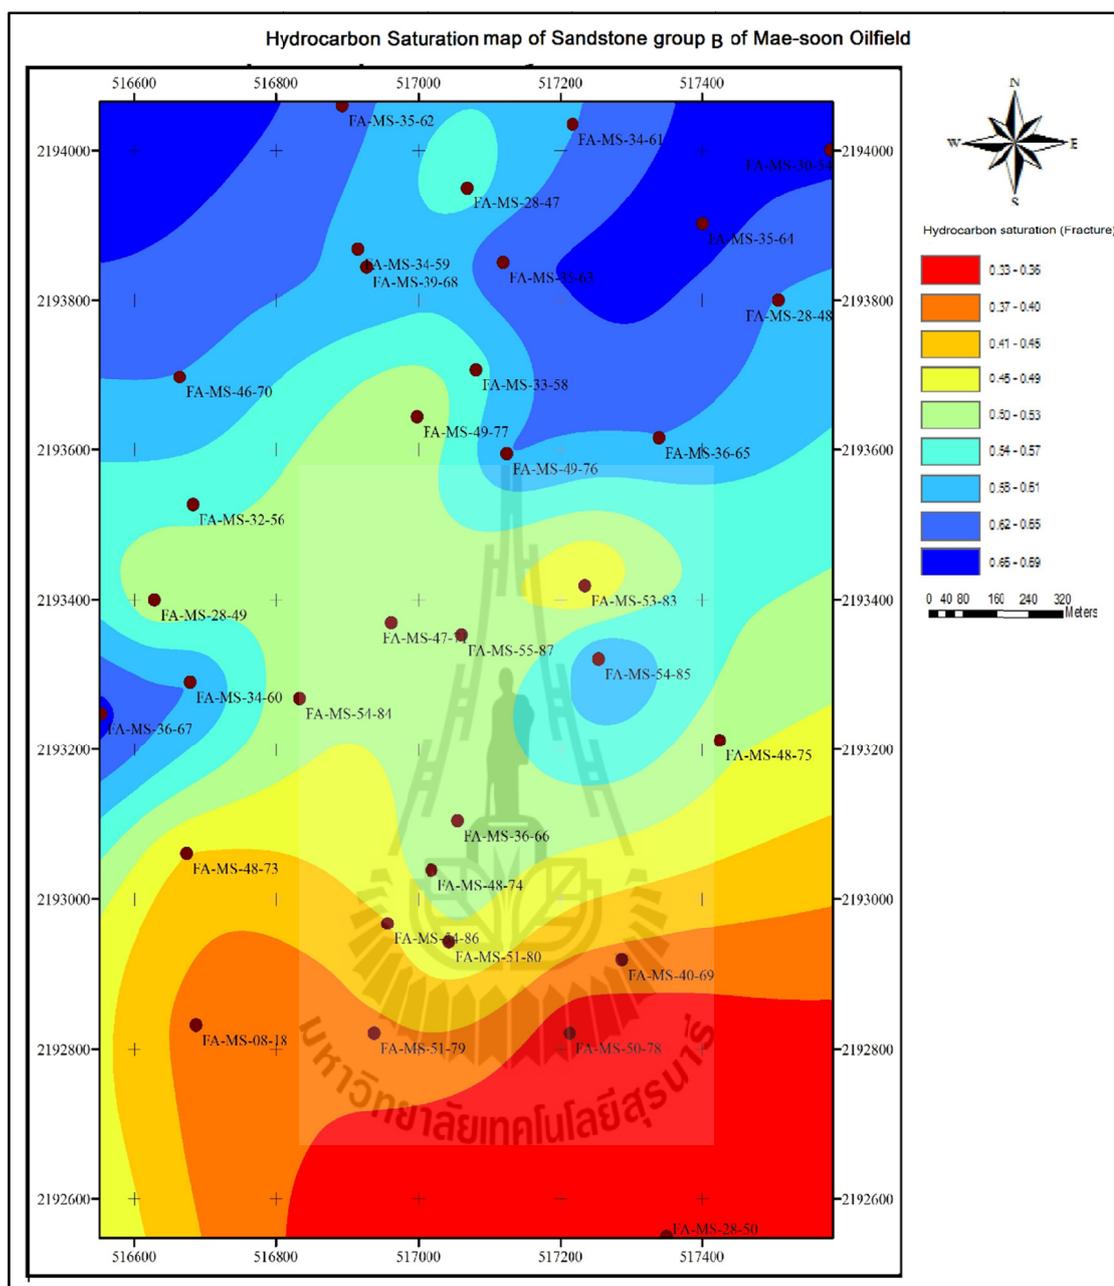

**Figure 4.62** Isopach map of sandstone Group B of Mae-Soon oil field.

**Figure 4.63** Porosity distribution map of sandstone Group B.

**Figure 4.64** Permeability distribution map of sandstone Group B.

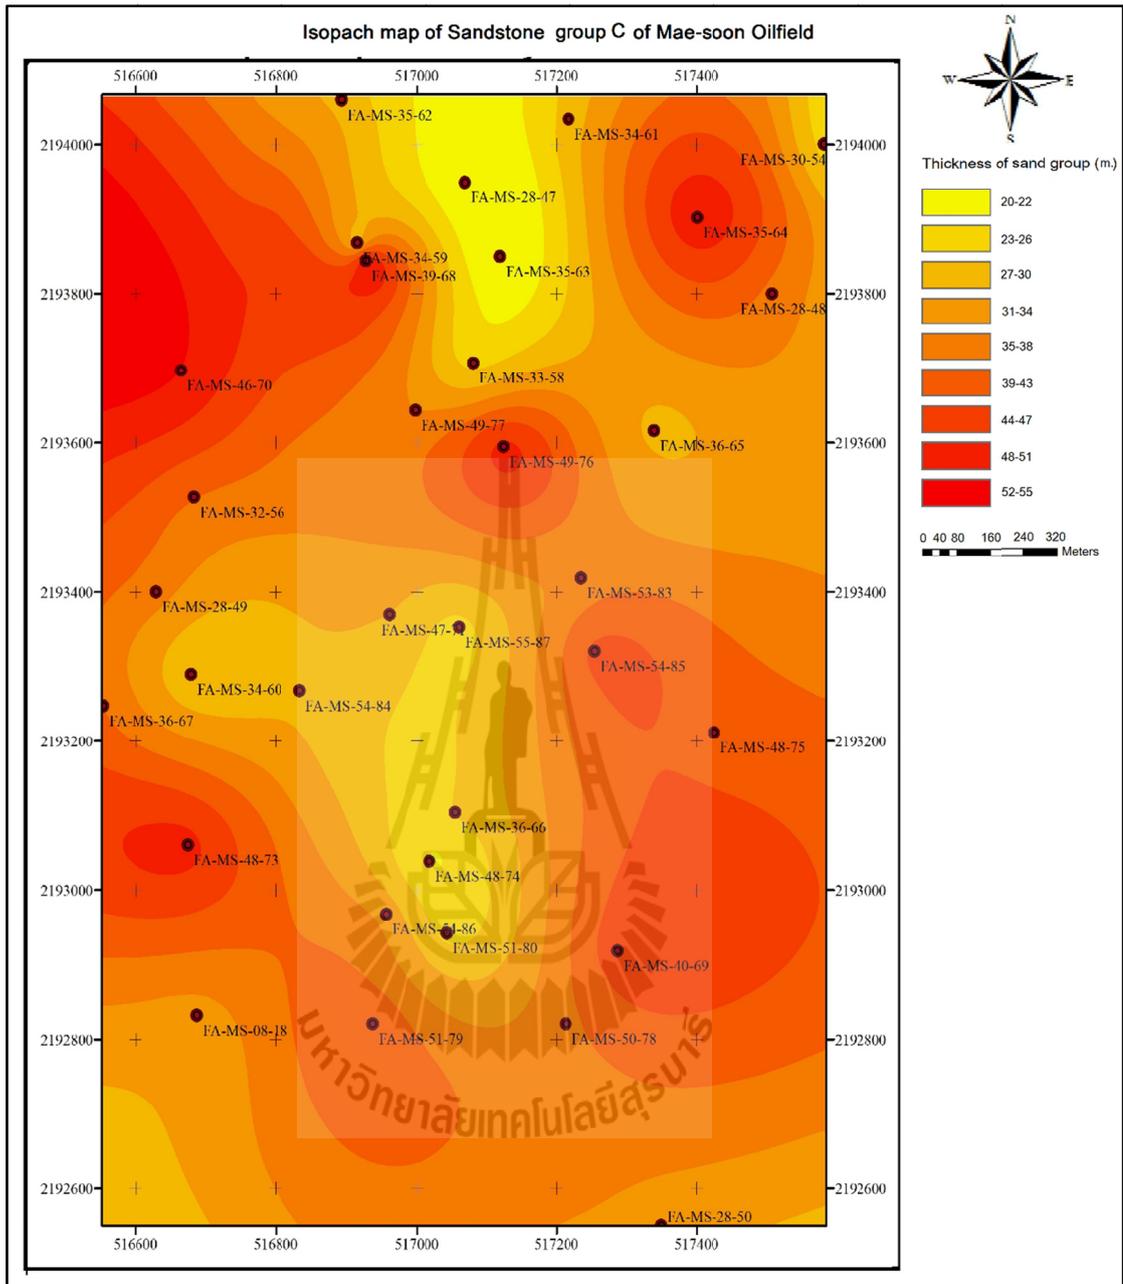

**Figure 4.65** Hydrocarbon saturation distribution map of sandstone Group B.

Sandstone Group C of Mae-Soon oil field was found at depth 2,326-3,434 feet. It has the thickest layer of about 163 feet and the thinnest layer of about 60 feet. The thick sandstone layer appears mostly all parts of the study area whereas the lower thickness shows only in the central part of the study area. This sandstone is Quartz Wacke type which is composed of very fine to medium-grained sand. The accumulation is also fining upward (Figure 4.66).

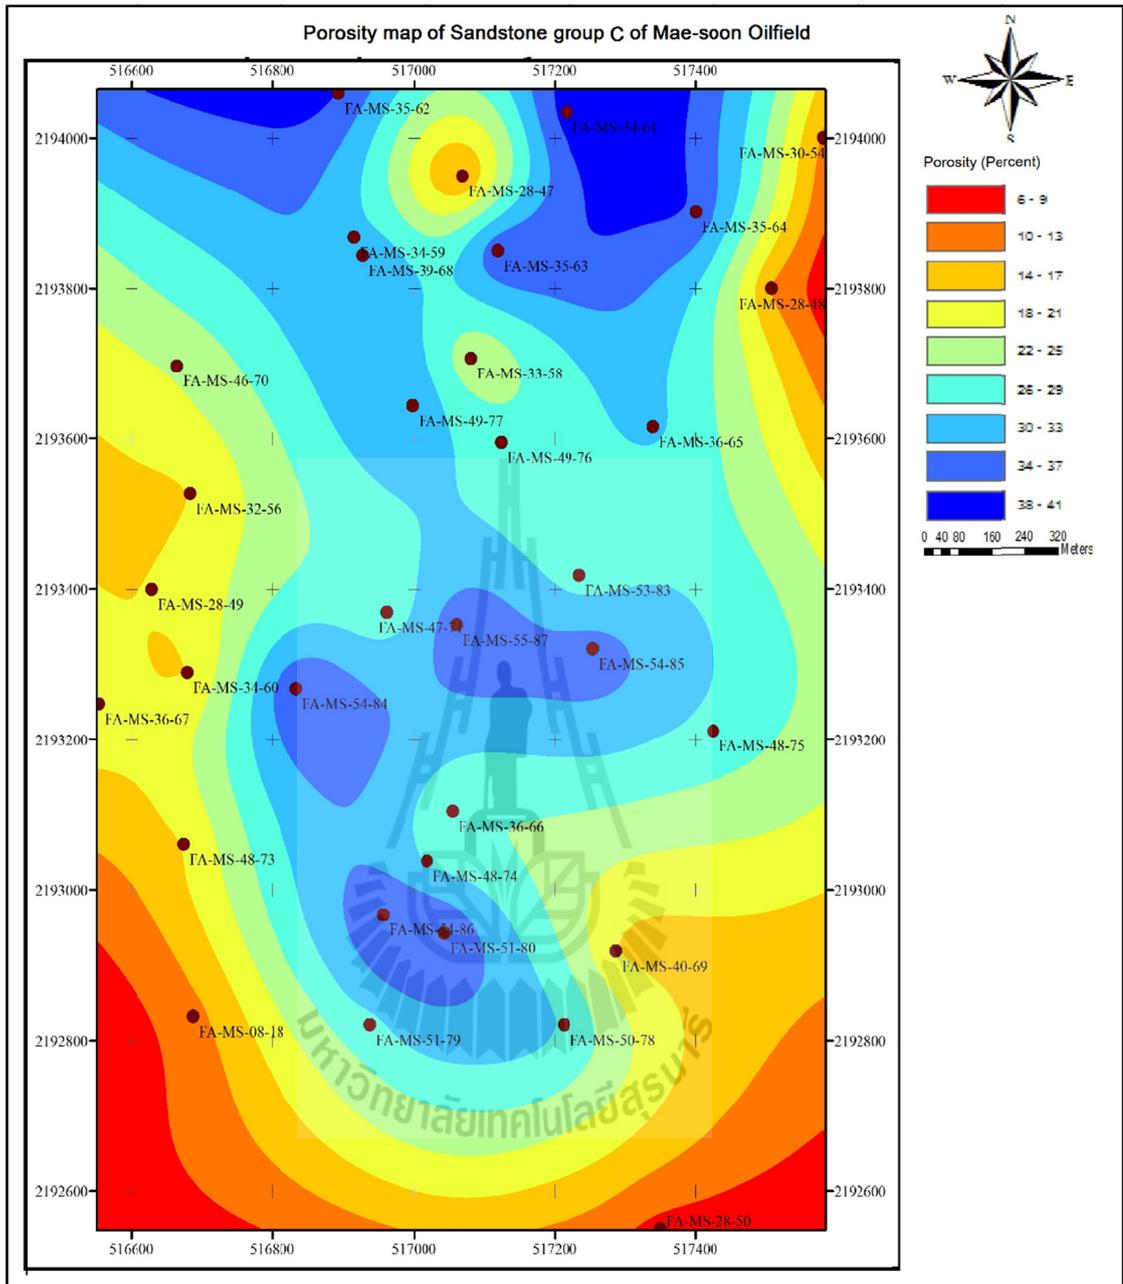

Porosity of sandstone Group C of Mae-Soon oil field is good - very good with an average porosity of 29.15%. The high porosity zones appear at the northern and the central part of study area whereas the lower porosity zones appear at the south and the west (Figure 4.67).

Permeability of sandstone Group C is good – very good with an average permeability of 599.41 milliDarcy. Like porosity, high permeability zones appear at the northern and the central part of study area whereas the lower porosity zones appear at the south and the west (Figure 4.68).

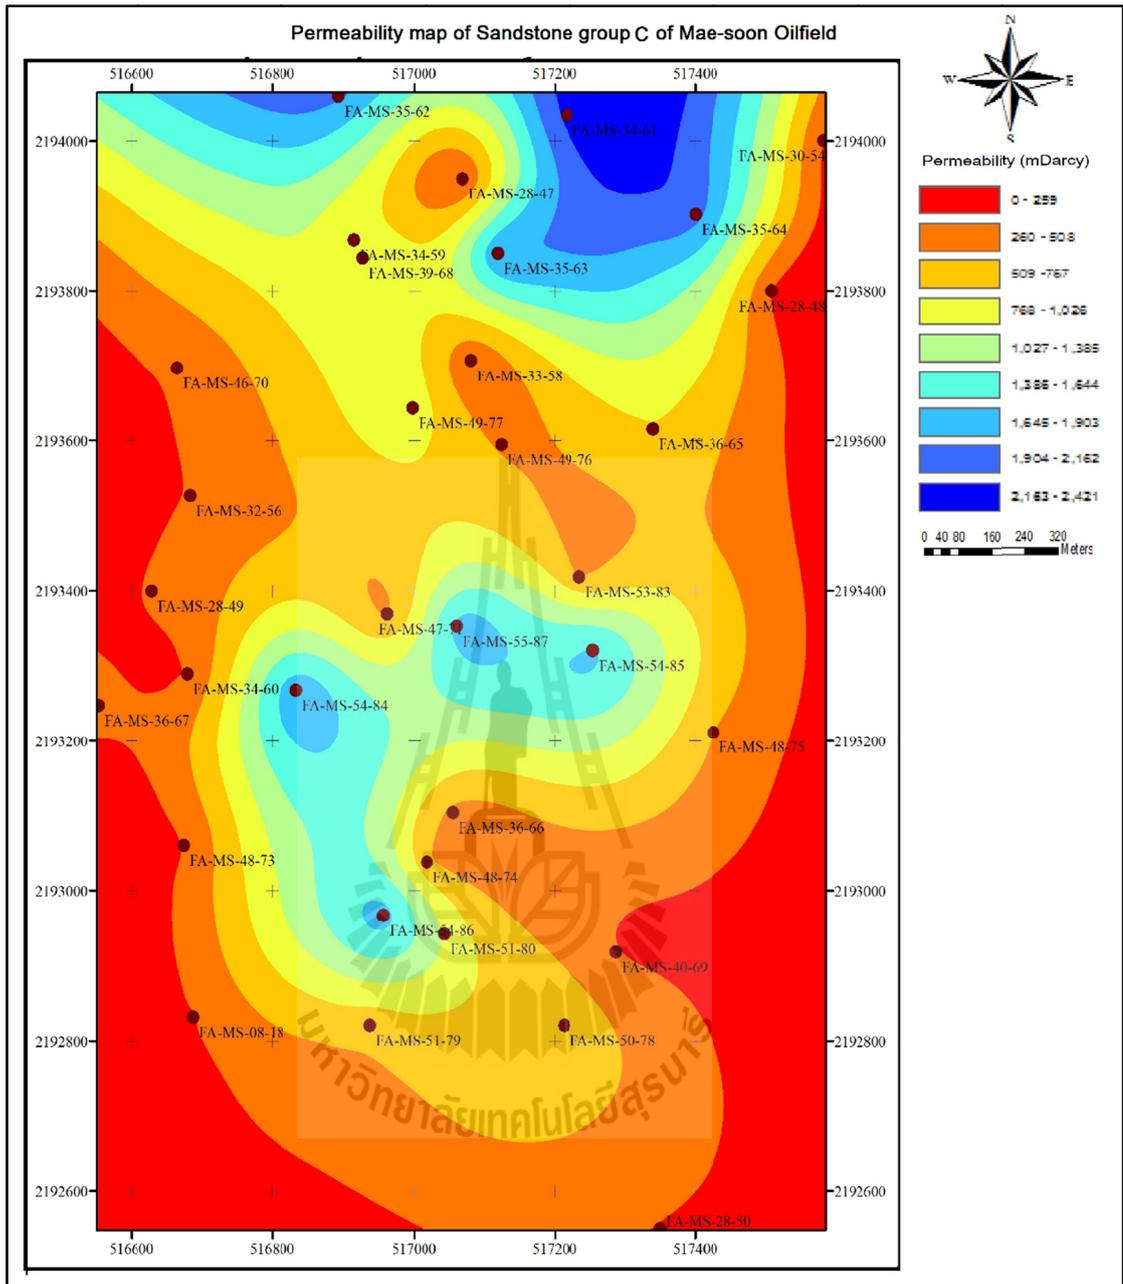

Hydrocarbon saturation of sandstone Group C is good - very good with an average of 0.52. Conforming to porosity and permeability, the high hydrocarbon saturation zones appear at the northern and the central part of study area whereas the lower porosity zones appear at the south and the west (Figure 4.69).

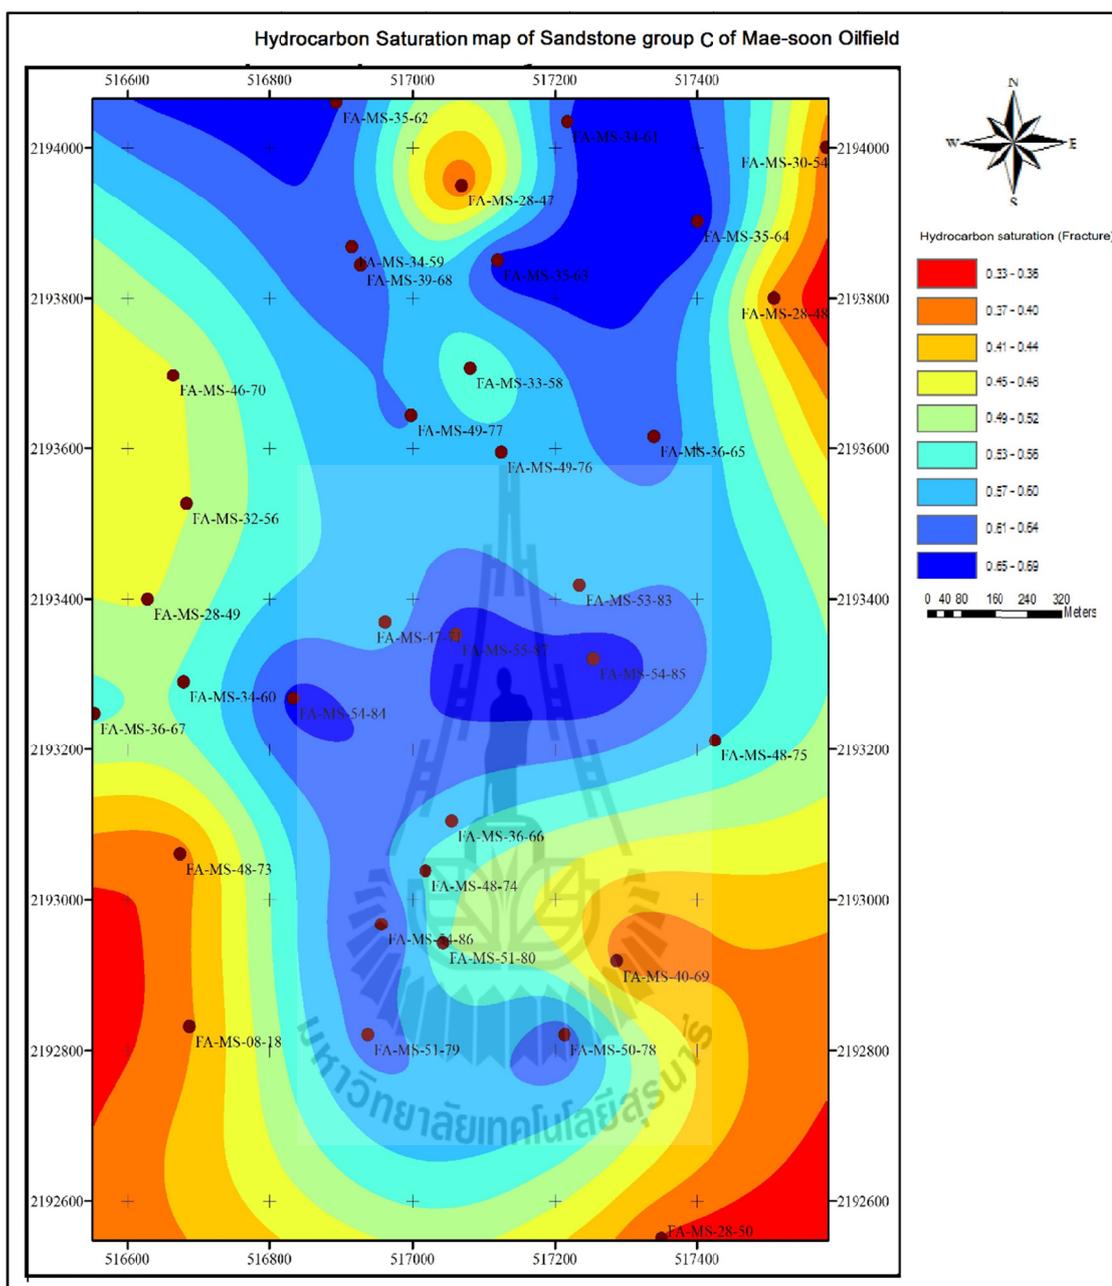

**Figure 4.66** Isopach map of sandstone Group C of Mae-Soon oil field.

**Figure 4.67** Porosity distribution map of sandstone Group C.

**Figure 4.68** Permeability distribution map of sandstone Group C.

**Figure 4.69** Hydrocarbon saturation distribution map of sandstone Group C.

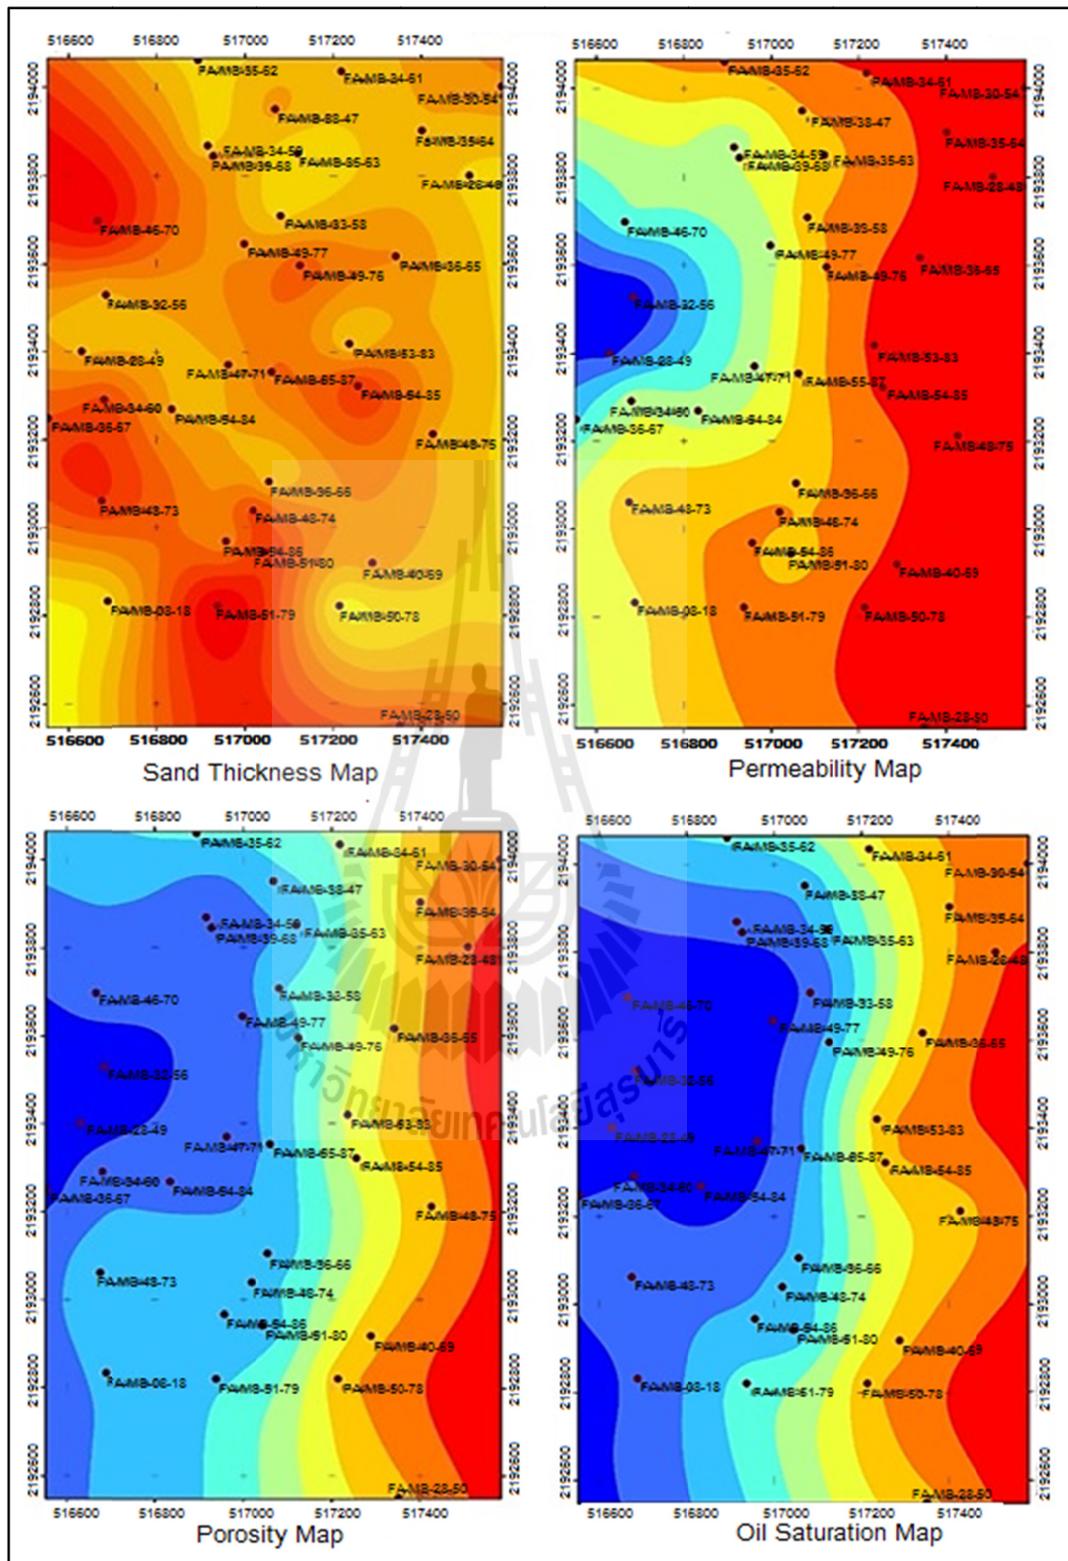

#### **4.4 Potential hydrocarbon-bearing zones of Mae-Soon oil field**

To identify the potential hydrocarbon-bearing zone of each grouped sandstone layer of Mae-Soon oil field, isopach, porosity, permeability and hydrocarbon saturation map of each grouped sandstone layer (Figure 4.70 to Figure 4.75) were analyzed all together, and then the boundary of the potential hydrocarbon-bearing zone of each grouped sandstone layer could be drawn. The identified potential hydrocarbon-bearing zones were ranked by its potential from high to low in the order number.

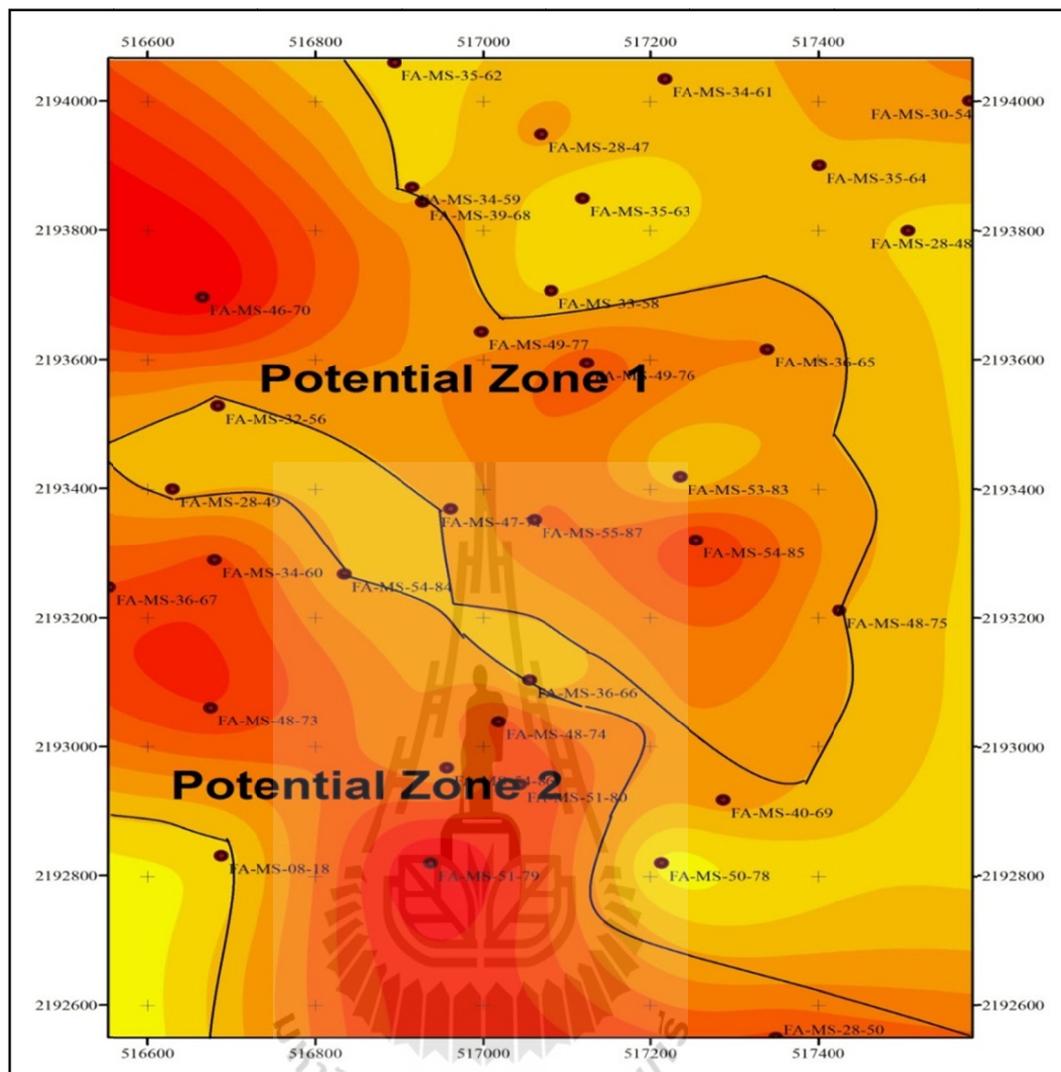

Sandstone group A (Figure 4.71) has two potential hydrocarbon-bearing zones. The first zone is located in the north-western and the central part whereas the second potential zone is located in the western and the southern part of the study area. Porosity and permeability of both zones are very good to excellent.

Sandstone group B (Figure 4.73) has three potential hydrocarbon-bearing zones. The first zone is located in the north-western part of the study area. The second potential zone is located in the eastern part whereas the third zone is located in the western part of the study area. Porosity and permeability of the first zone are highest and decreased in the second zone and the third zone respectively.

Sandstone group C (Figure 4.75) has four potential hydrocarbon-bearing zones. The first zone is located in the north-western part of the study area. The second potential zone is located in the north-eastern part. The third zone is located in the eastern part of the study area where as the fourth zone is located at the south-western part of the study area.

**Figure 4.70** Isopach, porosity, permeability and hydrocarbon saturation map of sandstone Group A.

**Figure 4.71** Hydrocarbon-bearing potential zone of sandstone Group A.

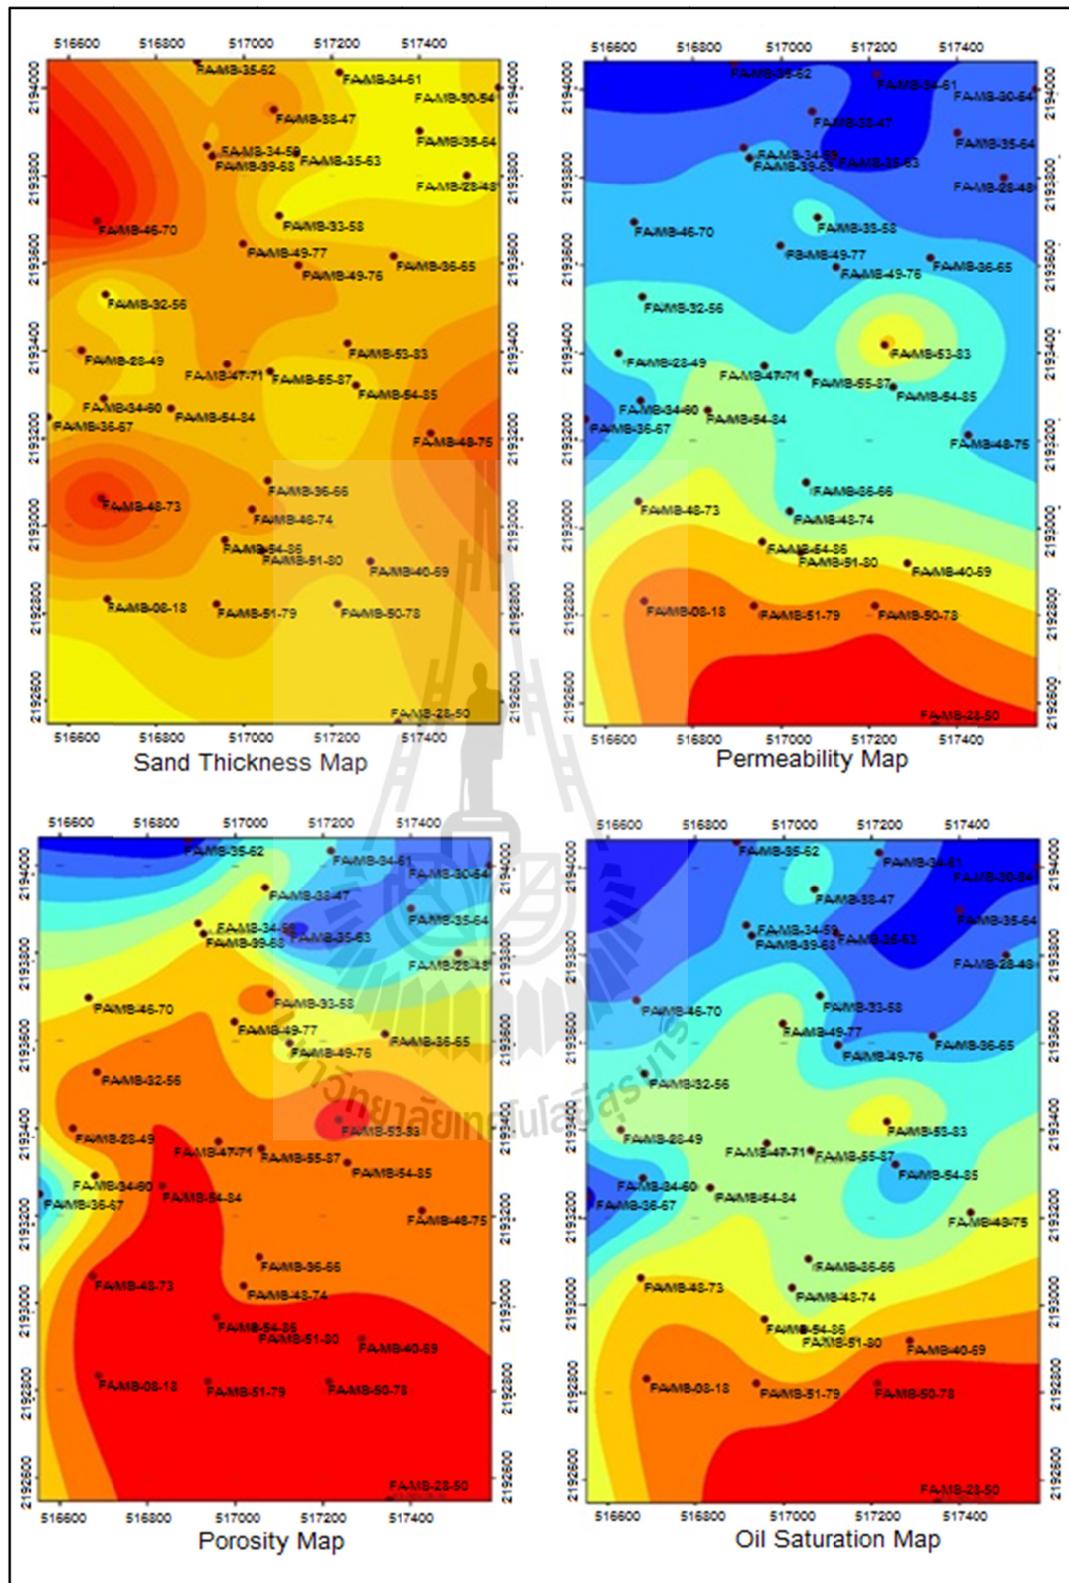

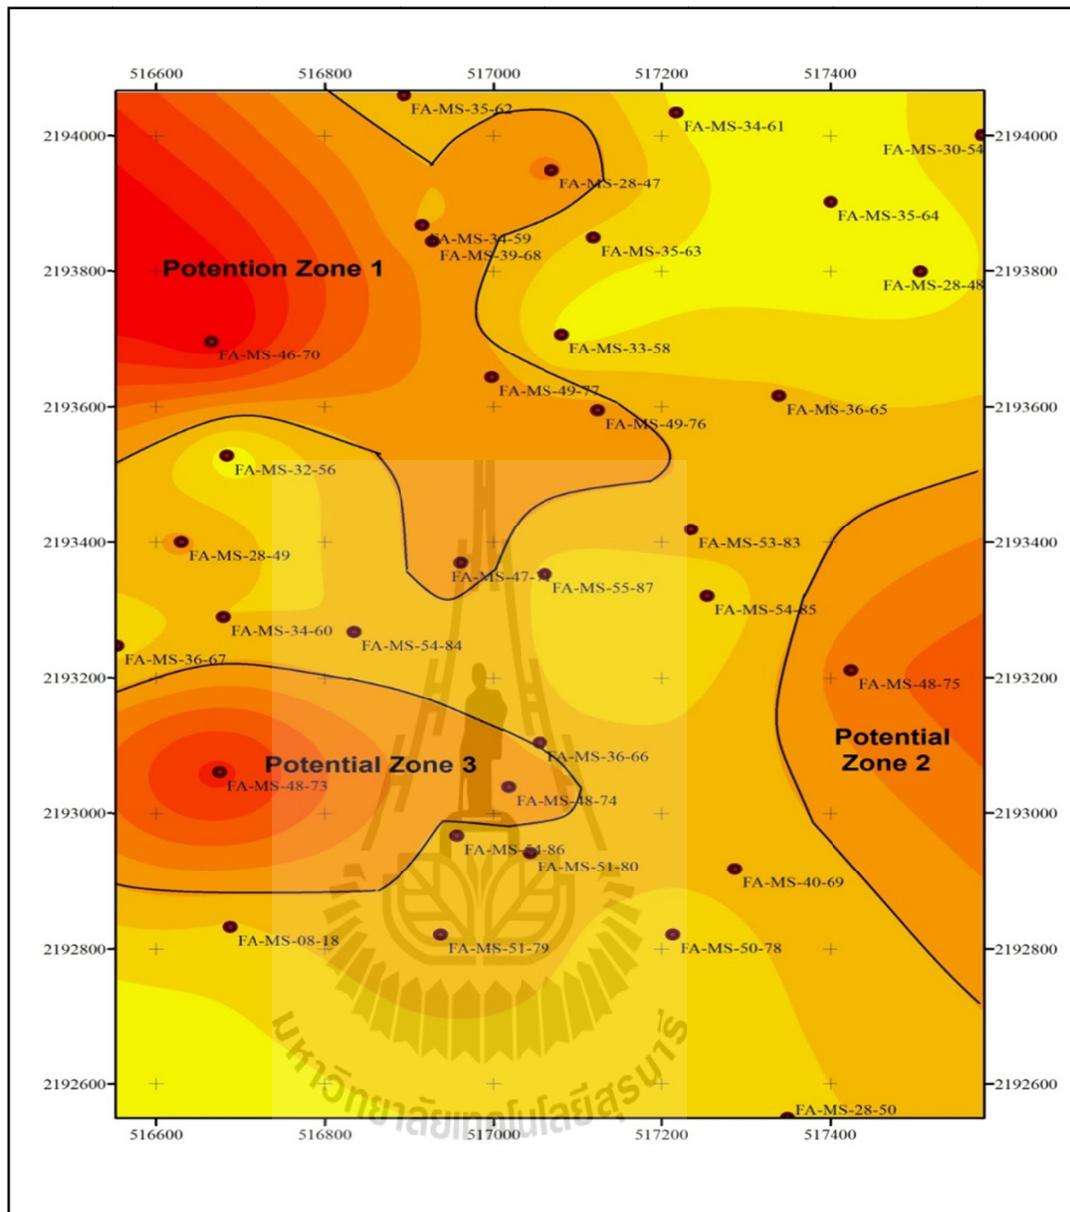

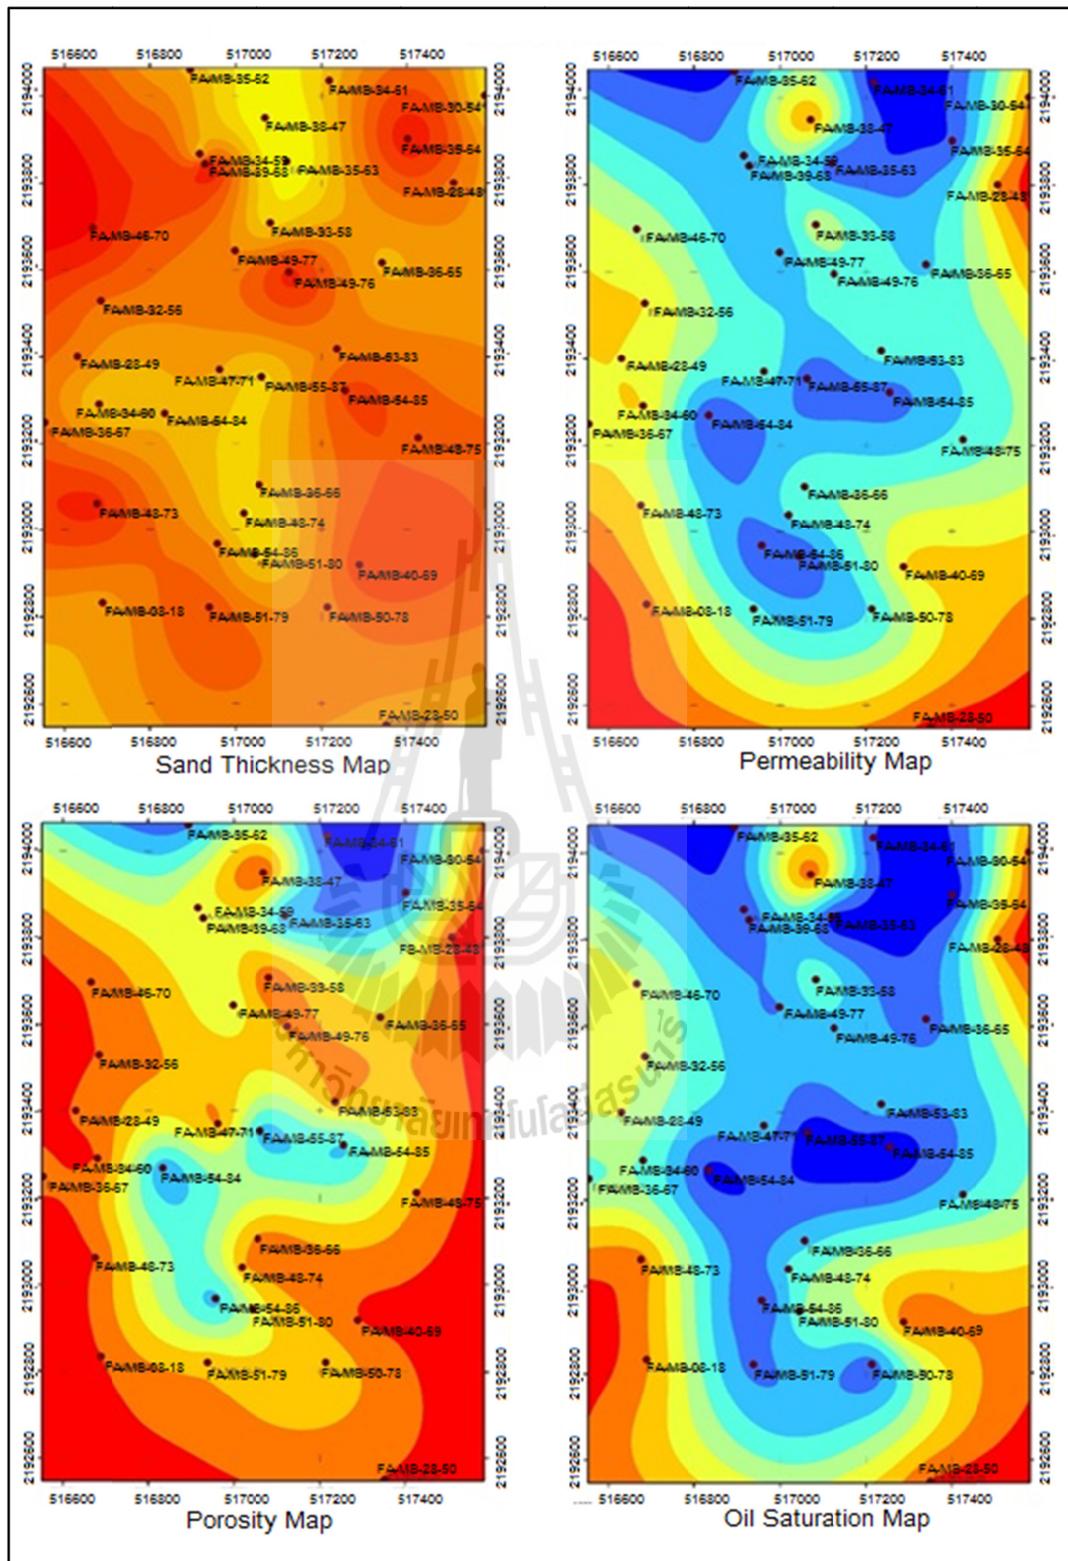

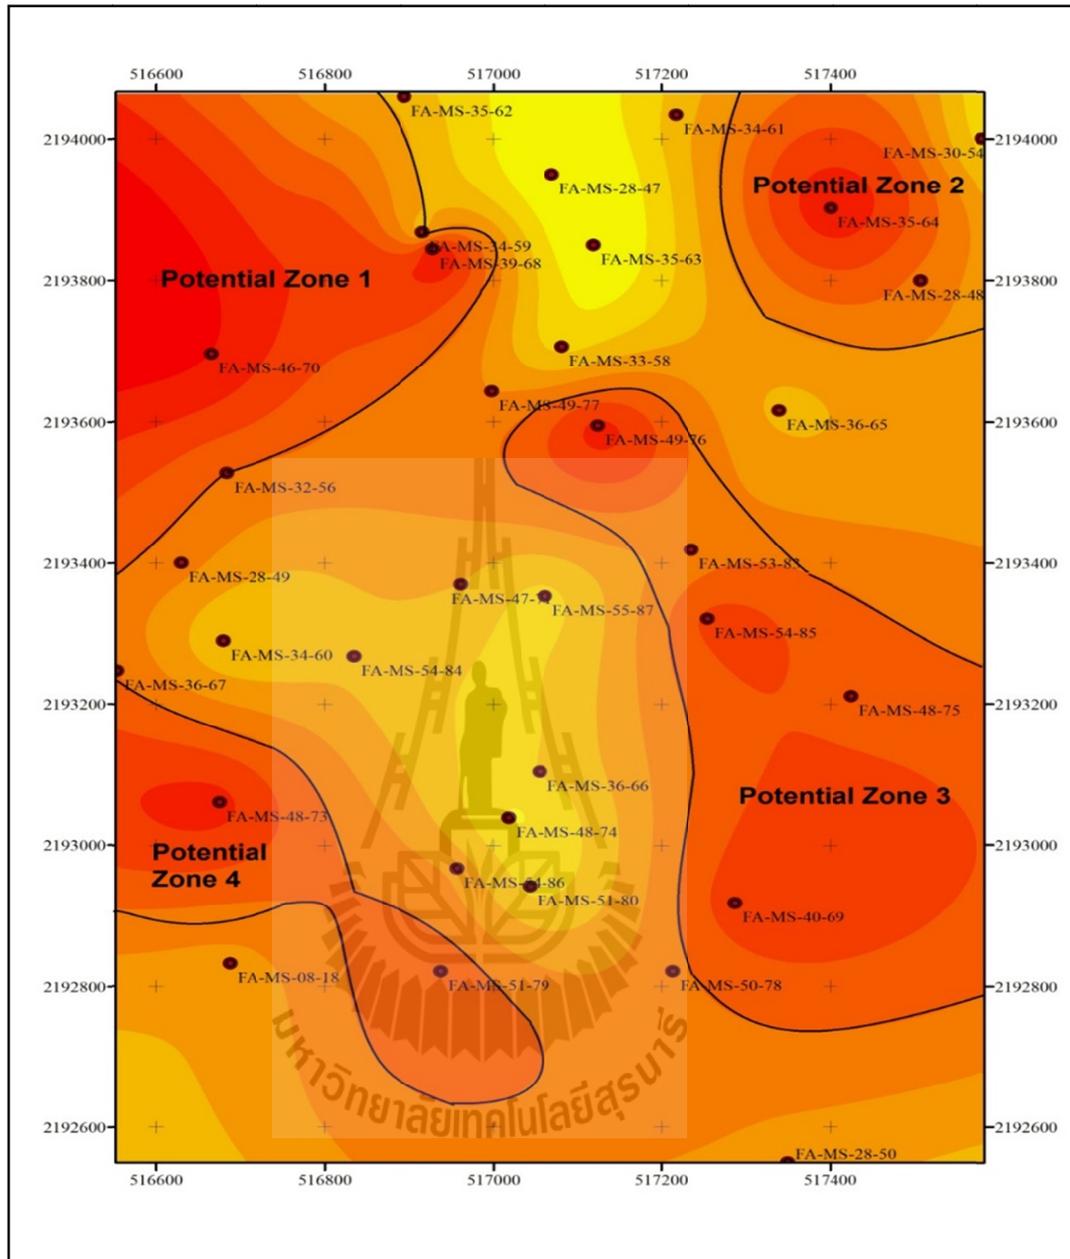

Figure 4.72 Isopach, porosity, permeability and hydrocarbon saturation map of sandstone Group B.

**Figure 4.73** Hydrocarbon-bearing potential zone of sandstone Group B.

**Figure 4.74** Isopach, porosity, permeability and hydrocarbon saturation map of sandstone Group C.

**Figure 4.75** Hydrocarbon-bearing potential zone of sandstone Group C.

#### 4.5 Three-dimensional map of the potential reservoirs

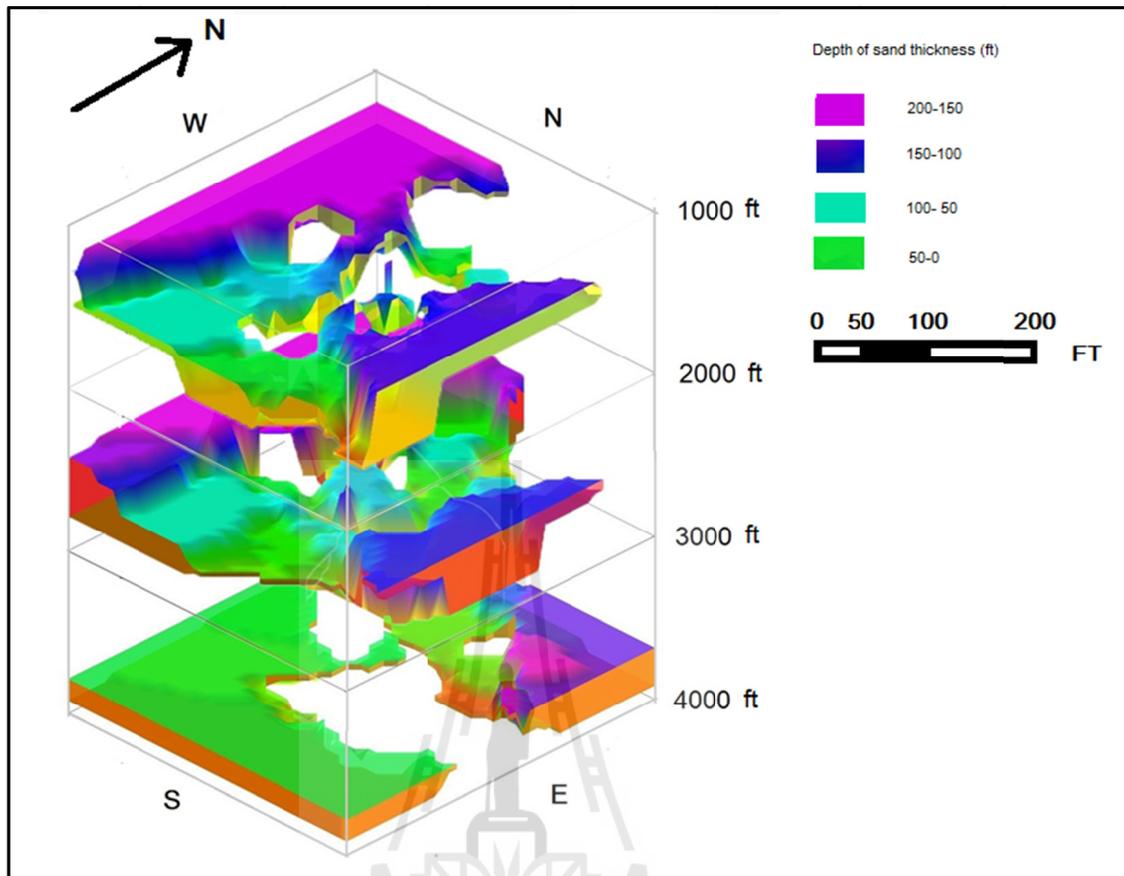

Results from literature reviews and wireline logging interpretation could be grouped 19 sandstone layers of Mae-Soon oil field into three main groups as presented in Table 4.1.

**Table 4.1** Three main grouped sandstone layer of Mae-Soon oil field.

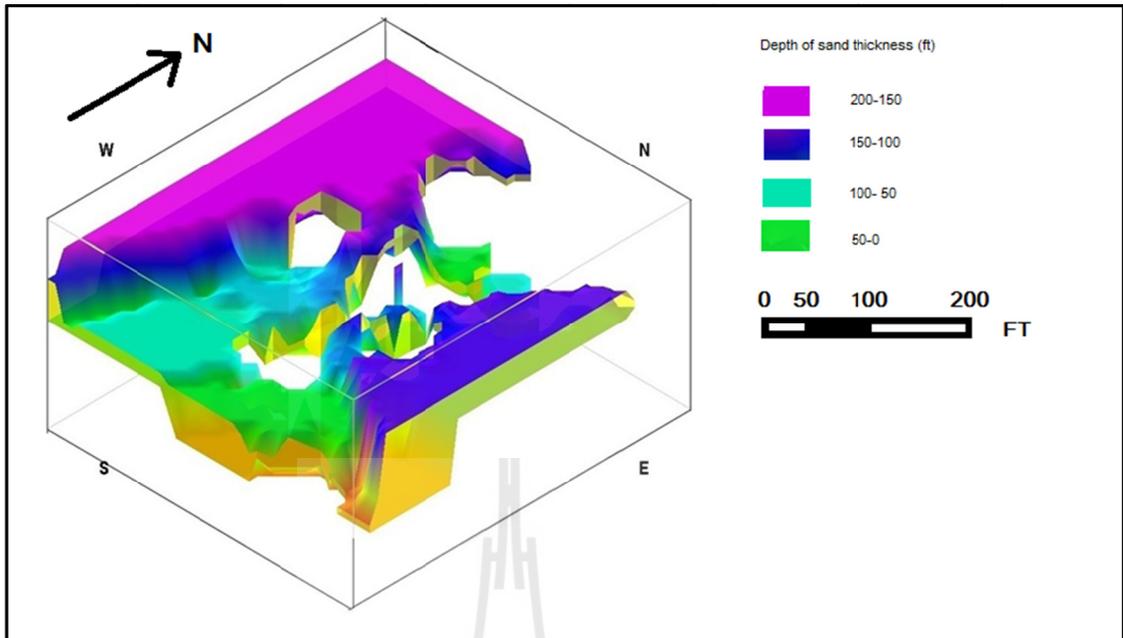

Group	A	B	C
<b>Kind of Sand</b>	Litic grey wacky	Litic grey wacky	Quartz wacky
<b>Grain Size</b>	Very fine - intermediate	Fine - Coarse	Very fine - intermediate
<b>Depth (feet)</b>	1,000-2,000	2,000-3,000	3,000-4,000
<b>Porosity (Percent)</b>	28.05	30.77	29.15
<b>Permeability (mDarcy)</b>	466.2643	492.0391	599.4069
<b>Oil Saturation (Fracture)</b>	0.55	0.52	0.57

It was found that sandstone layers of Mae-Soon oil field is fining upward in grain size. Sandstone group A and B are lithic greywacke whereas group C is quartz wacke. Porosity is highest in group B while permeability is highest in group C. Hydrocarbon saturation is similar in all groups.

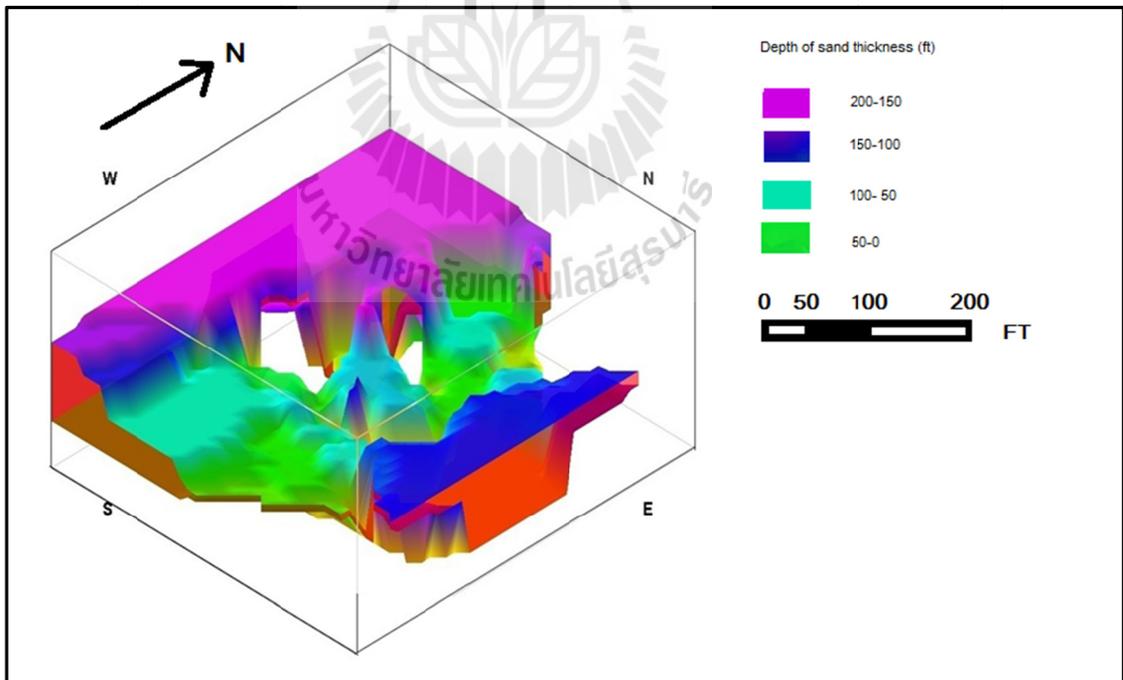

To illustrate the distribution of the three main groups of sandstone layers of Mae-Soon oil field, the three-dimensional model of each group were mapped as presented in Figure 4.76 to Figure 4.79, respectively.

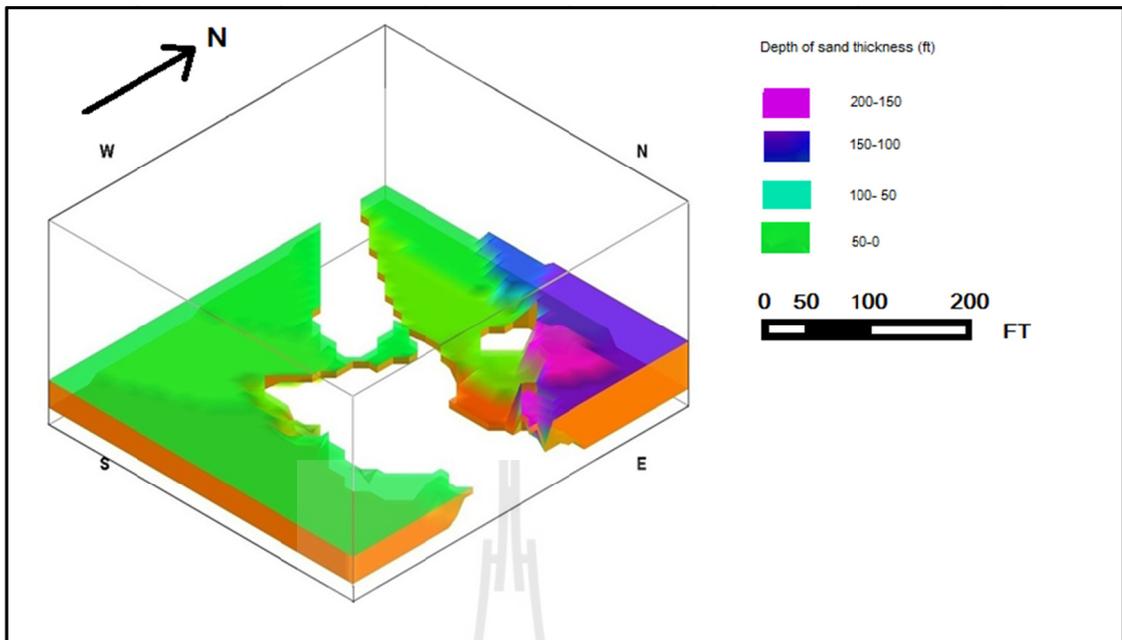

**Figure 4.76** Three-dimensional model of three main sandstone groups of Mae-Soon oil field.

**Figure 4.77** Three-dimensional model of sandstone Group A of Mae-Soon oil field.

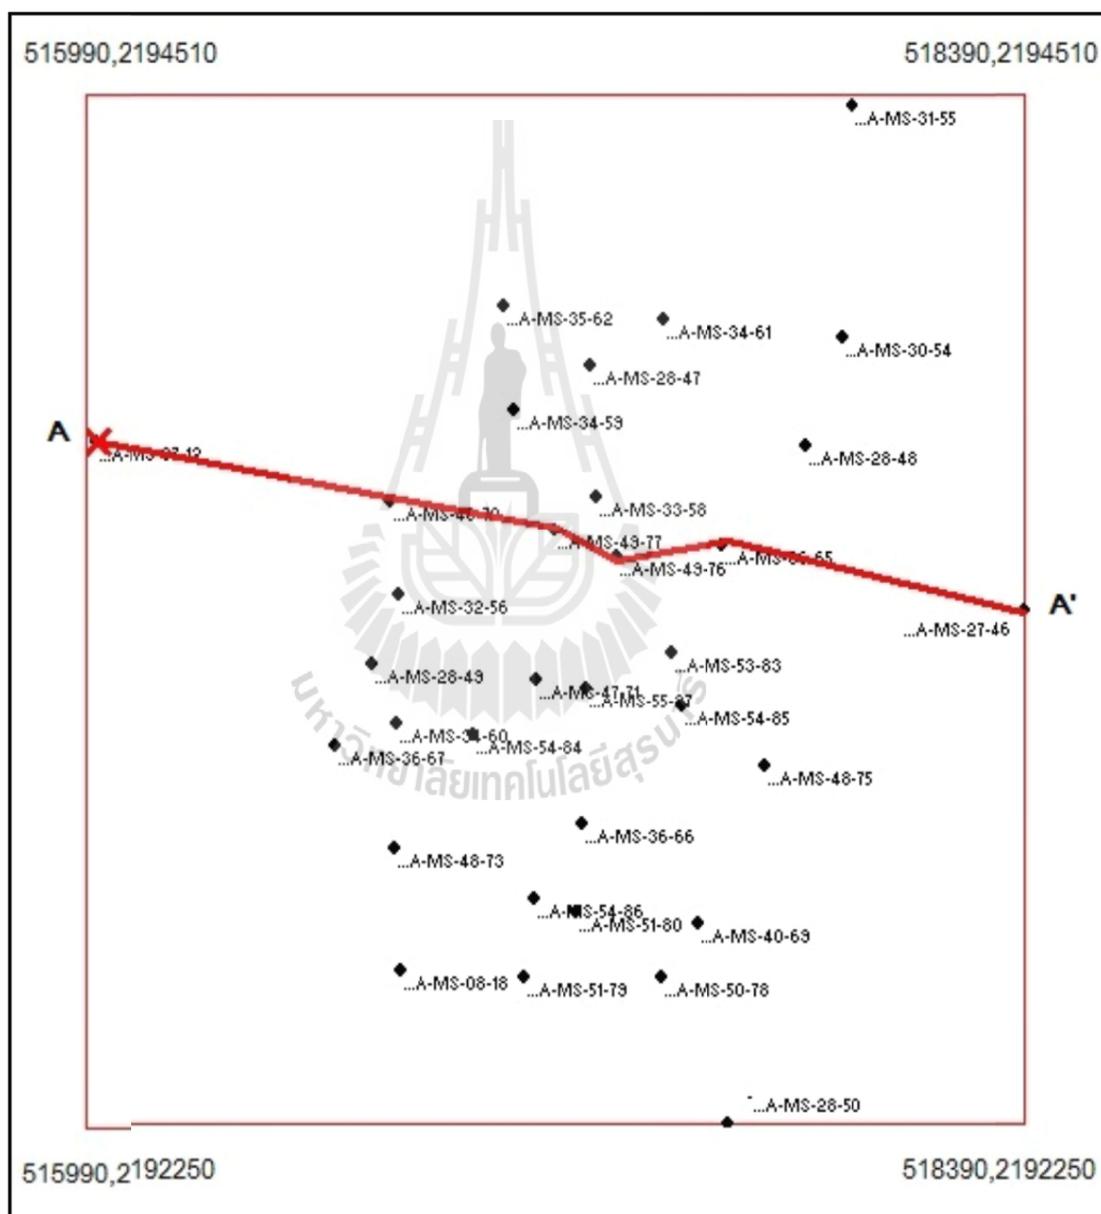

**Figure 4.78** Three-dimensional model of sandstone Group B of Mae-Soon oil field.

**Figure 4.79** Three-dimensional model of sandstone Group C of Mae-Soon oil field.

In addition to illustrate the stratigraphic correlation and subsurface structure of Mae-Soon oil field, geologic cross-section A-A' (west-east direction) and B-B' (north-south direction) had been made and are presented in Figure 4.80 to Figure 4.83, respectively.

**Figure 4.80** Location of geologic cross-section line A-A'.

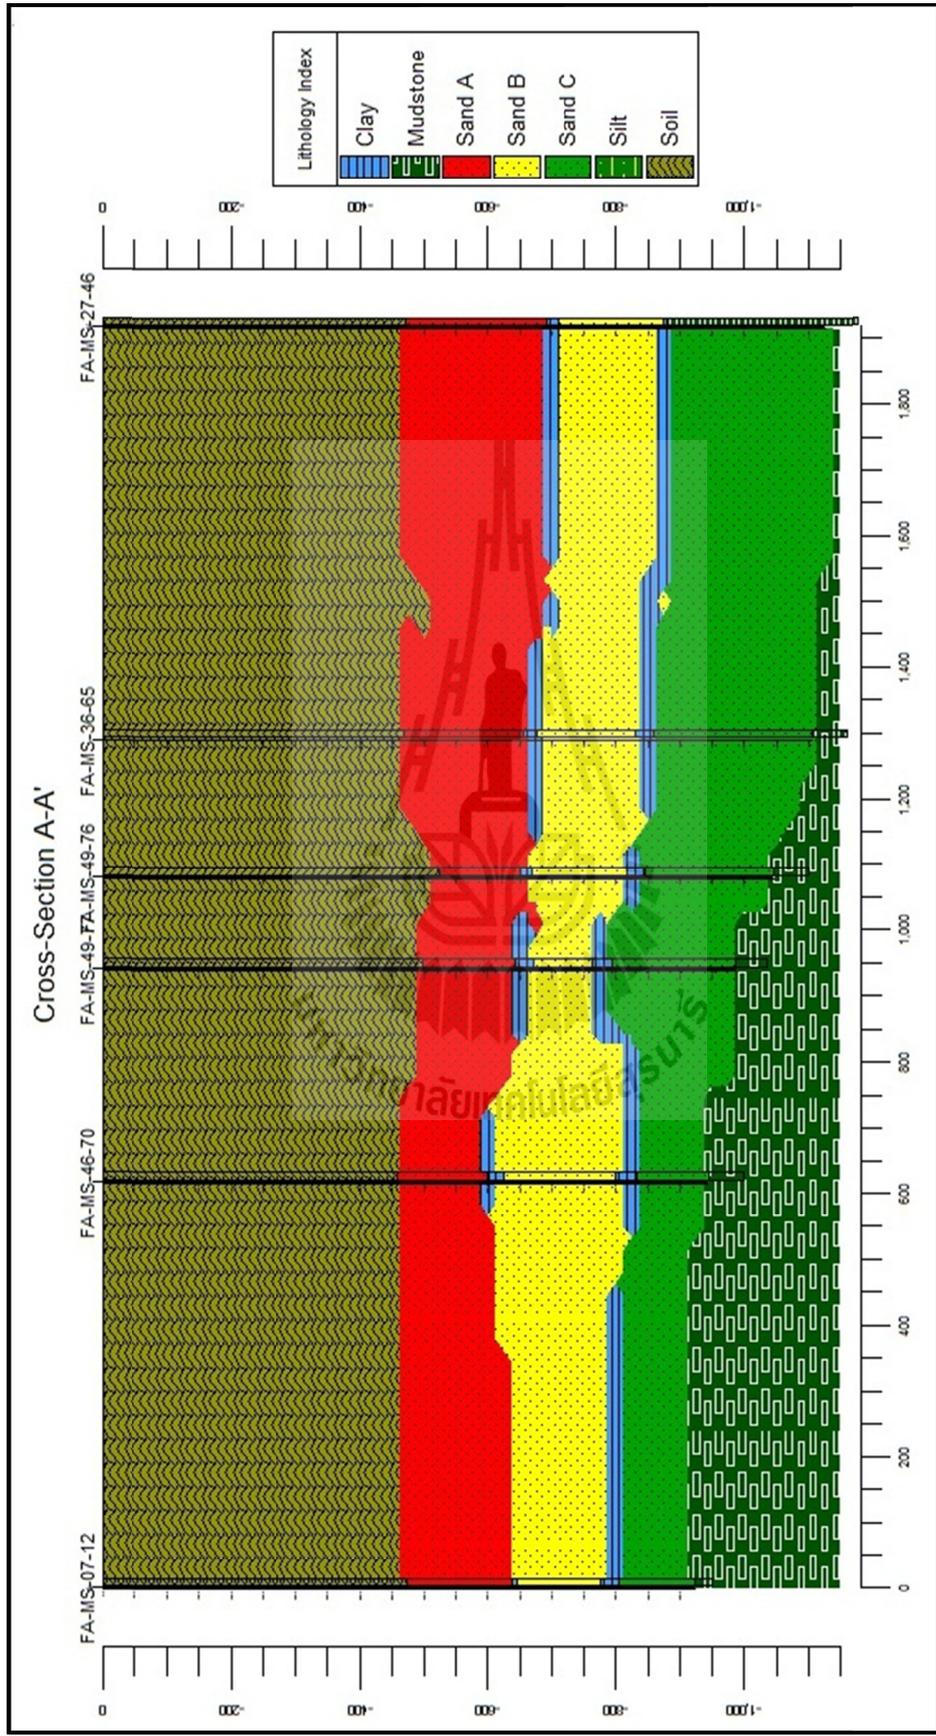

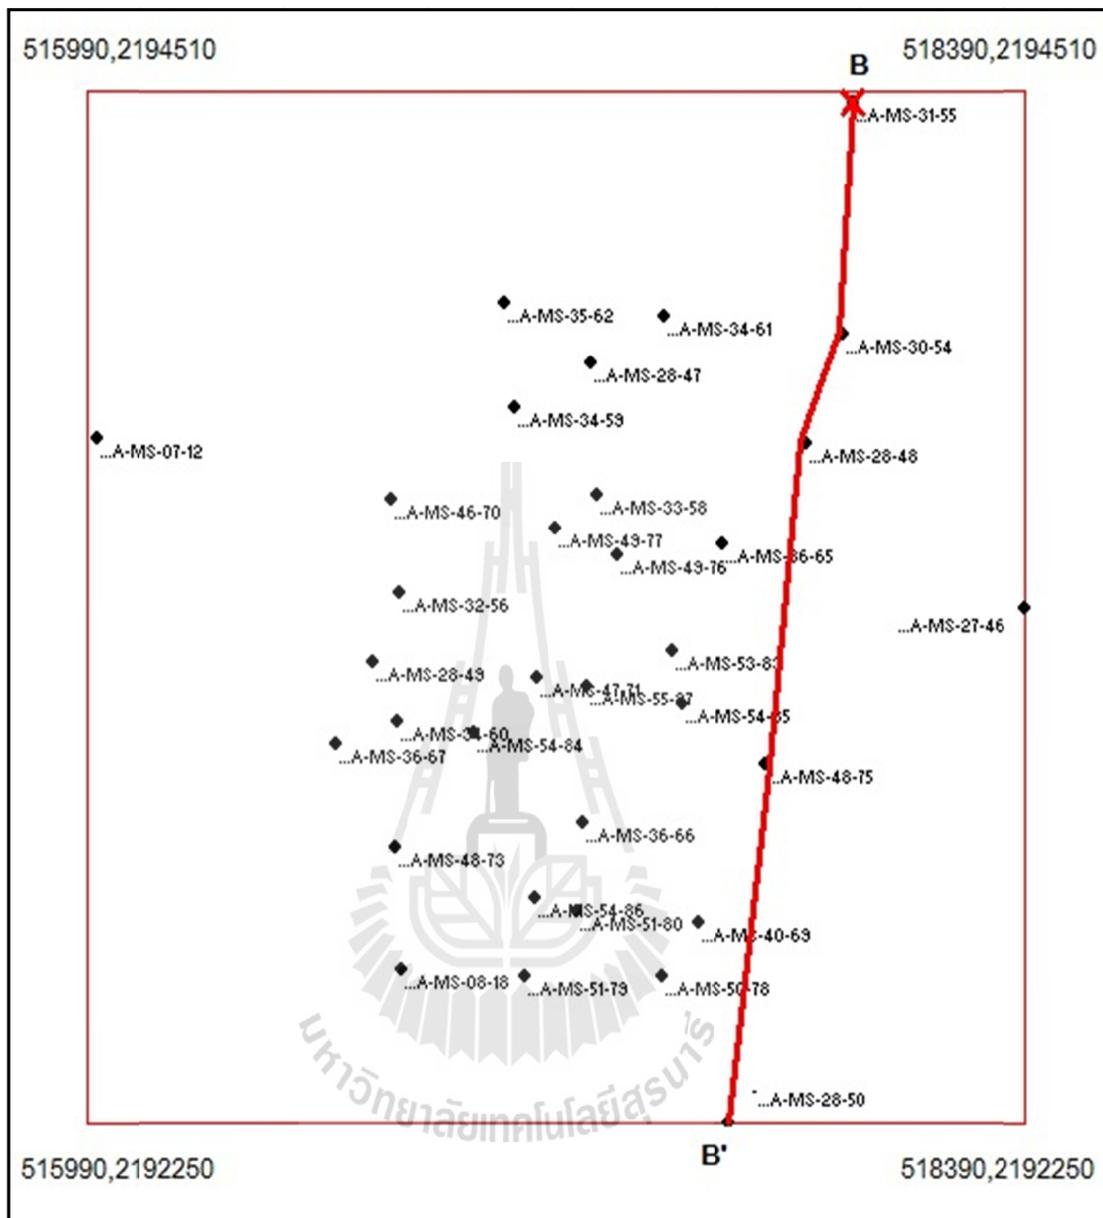

Figure 4.81 Lithologic cross-section line A-A'.

**Figure 4.82** Location of geologic cross-section line B-B'.

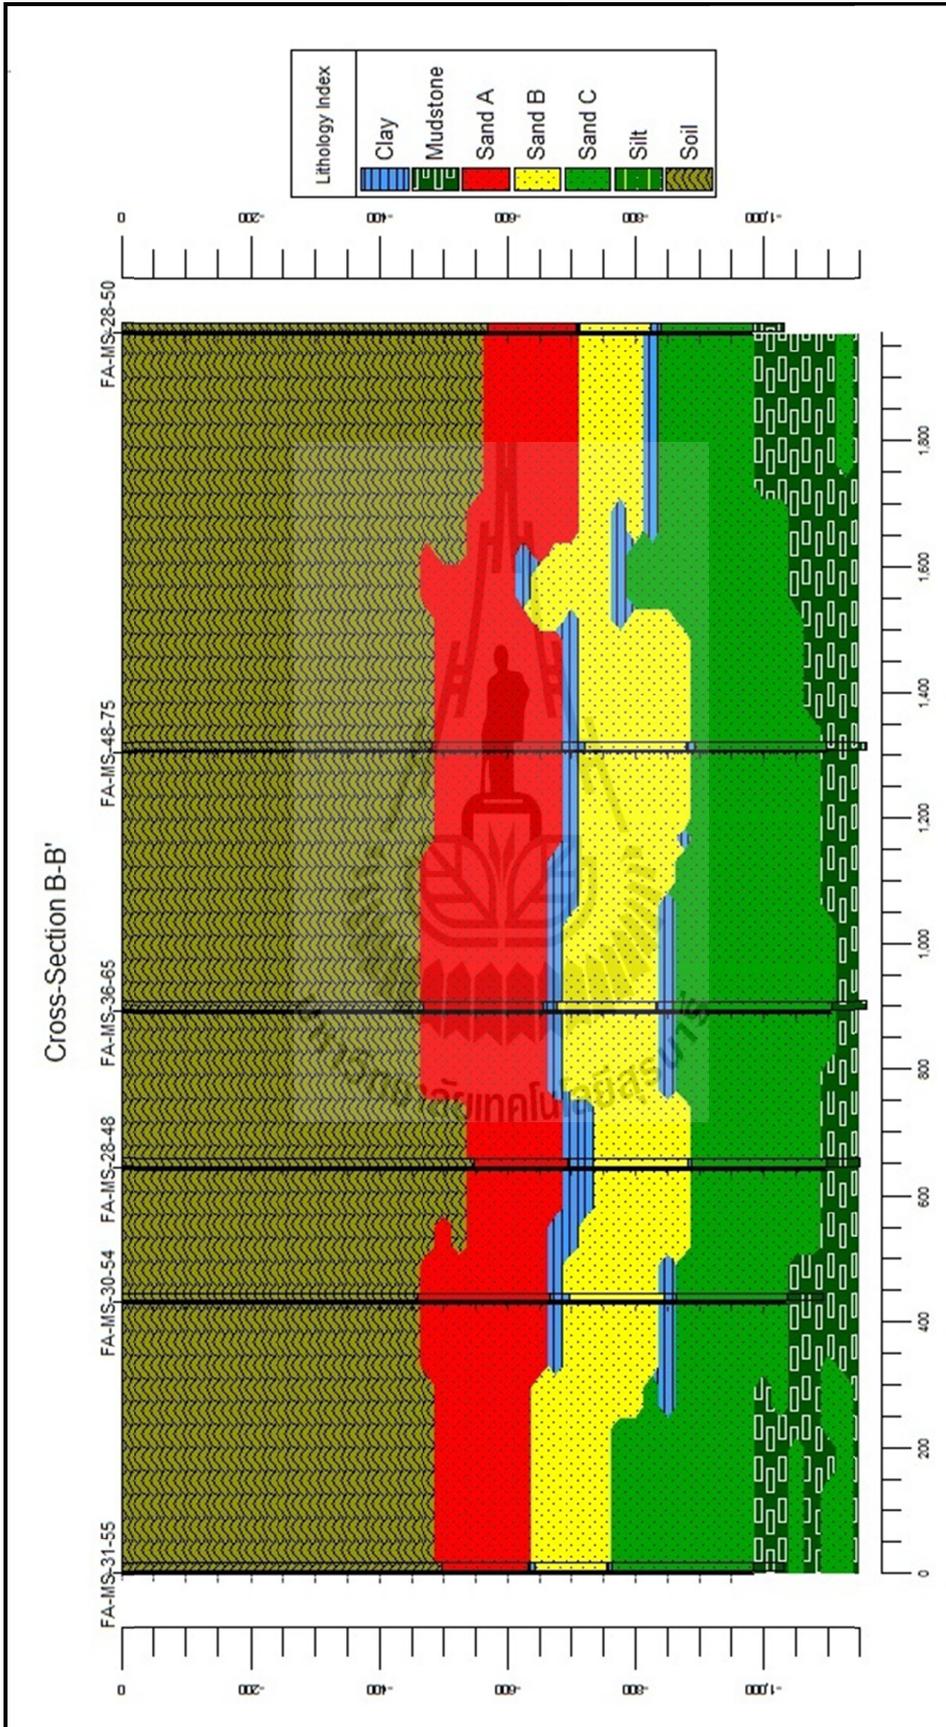

Figure 4.83 Lithologic cross-section line B-B'.

## CHAPTER V

### CONCLUSIONS, DISCUSSIONS AND RECOMMENDATIONS

#### 5.1 Conclusions

Results from literature reviews, petrophysical data, and wireline logging data interpretation of 33 boreholes drilled in Mae-Soon oil field could give some information about the distribution of oil reservoirs of this field and their properties as follows.

1. Sandstone reservoirs of this field can be classified into 19 main layers and can be grouped into 3 main groups as group A, B, and C based on lithology, petrophysical properties, and wireline log responses. Using sandstone type classification guideline based on resistivity data and mud logging data from DED and the quality of sandstone based on porosity and permeability from Dickker.

2. Porosity of sandstones layers of this field can be determined with the respect to depth by the linear equation as

$$\text{Depth} = 0.0089 (\text{Porosity}) + 25.415 \quad (5.1)$$

3. Relationship between porosity and permeability of sandstone layers of Mae-Soon oil field can be expressed by the linear equation as

$$\text{Permeability} = 0.0062 (\text{Porosity}) + 16.95 \quad (5.2)$$

4. Oil reservoir quality of Mae-Soon oil field is fair to excellent and suitable for hydrocarbon migration and storing since they have fair to excellent porosity and permeability.

5. Potential oil reservoirs orient and appear in various directions;

5.1 Sandstone group A has 2 potential hydrocarbon-bearing zones which are located in the north-western and south-western part of the field.

5.2 Sandstone group B has 3 potential hydrocarbon-bearing zones which are located in the north-western, eastern and western part of the field, respectively.

5.3 Sandstone group C has 4 potential hydrocarbon-bearing zones which are located in the north-western, north-eastern, eastern and south-western part of the field, respectively.

6. The shape and characteristic of sandstone layers as shown in the several maps revealed the deposit of sediment in the fluvial environment which occurred in different deposition time and different amount. Moreover, the uneven direction of water inlet and change of the river flow could cause the uneven and discontinuity of sediment deposition.

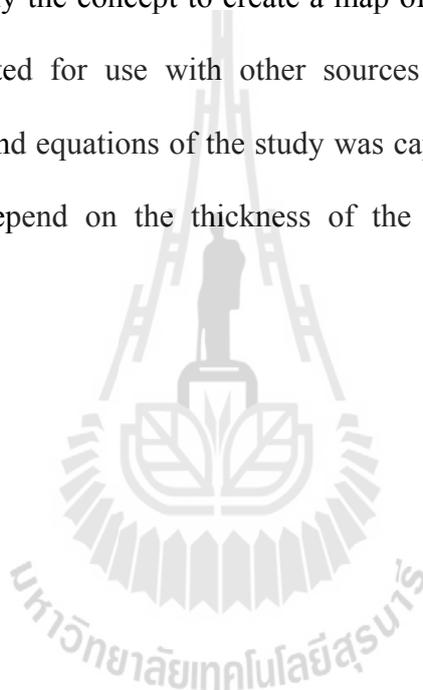

## 5.2 Discussions

This research did not study the stratigraphic correlation of Mae-soon oil field which also has an important role in clarifying the distribution of the potential sandstone reservoirs since it much affects to the direction of migration, seal and trapping mechanism of hydrocarbon in the reservoir. Thus, this is might be effected to the reliability of the study results. Therefore, for the future study, more information on stratigraphic correlation should be taken into account to eliminate some uncertainty. However, results from this study still give some benefit and information to the Defense

Energy Department since they can help in oil production operation planning of this filed.

### **5.3 Recommendations**

Because Fang basin is not only Mae-Soon oil field, a significant oil only. But there are other sources of oil, such as San-Sai oil field, Pong-Nok oil field etc. Therefore, it can apply the concept to create a map of the distribution of the oil layer and evaluation adapted for use with other sources of oil reservoir. It also can contribute concepts and equations of the study was capped in order to create the map. However, it must depend on the thickness of the oil reservoir and oil reservoir properties.

## **BIOGRAPHY**

Mr. Makara Laikanok was born on September 7, 1988, in Surat Thani Province, Thailand. He received his Bachelor's Degree in Engineering (Geotechnology) from Suranaree University of Technology in 2009. He continued with his graduate study in the Petroleum Engineering Program, Institute of Engineering, Suranaree University of Technology.
